**Ankylosing Spondylitis** This rheumatologic condition of the spine is due to inflammation at the sites of ligamentous insertions into bone that leads to an intense calcification at these and adjacent sites. The sacroiliac joints and lumbar spine are most affected, as discussed on page 180, but as the disease advances, the entire spine becomes fused and rigid. The biomechanics of the rigid spine make it susceptible to fracture. The most common complication is a spinal stenosis and cauda equina syndrome. Bartleson and associates described 14 patients (and referred to 30 others in the medical literature) who, years after the onset of spondylitis, developed sensory, motor, reflex, and sphincteric disorders referable to L₄, L₅, and the sacral roots. Surprisingly, the spinal canal was not narrowed but instead the caudal sac was actually dilated. Confavreux et al have presented evidence that enlargement of the lumbar dural sac is due to a defect in resorption of the CSF. There are usually arachnoidal diverticulae on the posterior root sleeves, but no other explanation can be given for the radicular symptoms and signs. Surgical decompression has not benefited the patients, nor has corticosteroid therapy. This condition occasionally occurs at higher levels and gives rise to a myelopathy. Our experience includes cases with symptoms related to the cervical roots with diverticulae of dural nerve sheaths.

The most hazardous complication of ankylosing spondylitis is compression of the cord, from seemingly minor trauma that has resulted in fracture-dislocation of the cervical (or lumbar) vertebrae. Fox and colleagues from the Mayo Clinic treated 31 such patients in a 5-year period; the majority of unstable fractures that required surgical fixation were in the cervical region, and several patients had fracture-dislocations at two levels. The instability at the upper spinal levels may be difficult to detect radiologically, and caution should be observed in allowing patients to resume full activity after a neck injury if the cervical spine is seen to be involved by spondylitis. Careful flexion and extension x-ray views usually, but not always, demonstrate the instability.
As alluded to earlier, multiple arachnoid cysts in the thoracic or lumbar region have been associated with ankylosing spondylitis and with Marfan syndrome.

**Rheumatoid Arthritis** The spinal changes of rheumatoid arthritis differ somewhat from those of ankylosing spondylitis although the latter too may be a cause of atlantoaxial dislocation (see further on under “Anomalies at the Craniocervical Junction.”) The ligaments that attach the odontoid to the atlas and to the skull and the joint tissue are weakened by the destructive inflammatory process. The subsequent dislocation of the atlas on the axis may remain mobile or become fixed and give rise to an intermittent or persistent mild to moderate paralysis or quadriparesis. Similar effects may result from a forward subluxation of C4 on C5 (see Nakano et al.). Atlantoaxial dislocation is known to be a cause of collapse and sudden death. If the upper cervical cord is compressed, the odontoid process must be removed and C1–C2 decompressed and stabilized. Other levels of the spine are less frequently affected.

**Ossification of the Posterior Longitudinal Ligament (OPLL)** Compressive cervical myelopathy due to this unusual process occurs almost exclusively in patients of Japanese extraction and has been demonstrated to us as an almost mundane finding by colleagues in Hawaii. The clinical signs are much the same as those of cervical spondylosis, but the radiologic appearance of cancellous bone along a segment of the posterior longitudinal ligament is unique. The ligamentous calcification can be seen on plain films, CT scan, and MRI and may be mistaken for spondylotic change. The ossified areas may enlarge enough to form islands of bone marrow. Laminoplasty with enlargement of the spinal canal has been successful.

**Cervical Dural Sac Myelopathy (Hirayama Disease, Juvenile Muscular Atrophy of the Distal Upper Limb)** This unusual myelopathy has usually been considered with the motor neuron disorders because of its characteristic features of chronic wasting of one hand and forearm without sensory changes or long tract signs. Hirayama pointed out that in the young men who were affected, the mechanism of cord damage may be a buckling of the dorsal dural sac and intermittent anterior displacement and ligation of the cord during flexion of the neck.

The muscles innervated by C7, C8, and T1, encompassing mainly the hand and forearm, are affected on one side or bilaterally, but always asymmetrically. There are few or no fasciculations and no sensory changes; the painless loss of power and muscle bulk proceeds smoothly over several years, giving the impression of a degenerative condition. MRI or CT myelogram performed with the neck flexed, as described by Hirayama and Tokumaru, shows the cervical cord to be atrophic with signal changes in the anterior parts of the cord and confirms the diagnosis of compression by the buckled dura. We have examined three such patients in the past 5 years and can corroborate their claim from observation of MRI with the patient placed in a flexed-neck position. Presumably, this configuration causes ischemia of the anterior gray matter, but this has not been proved. Others have reported the syndrome in the absence of this structural configuration (Willeit et al.). Two of our patients had long swan-like necks. What is most important about this process is the degree of recovery afforded by partial vertebrectomy and by similar surgical approaches that accomplish decompression of the lower cervical cord.

**Paget Disease of the Spine (Osteitis Deformans)** Enlargement of the vertebral bodies, pedicles, and laminae in Paget disease may result in narrowing of the spinal canal. The clinical picture is one of cord compression. Plasma alkaline phosphatase concentrations are high, and the typical bone changes are seen in radiographs. Usually several adjacent vertebrae of the thoracic spine are affected. Other parts of the skeleton are also involved (see later), which facilitates diagnosis. Posterior surgical decompression, leaving the pedicles intact, is indicated if there is sufficient stability of the vertebral bodies to prevent collapse. Medical management includes the use of nonsteroidal anti-inflammatory drugs for persistent pain; calcitonin to reduce pain and plasma levels of alkaline phosphatase; and cytotoxic drugs such as plicamycin and etidronate disodium to reduce bone resorption (see Singer and Krane).

**Other Spinal Abnormalities with Myelopathy**

The spinal cord is obviously vulnerable to any vertebral maldevelopment or disease that encroaches upon the spinal canal or compresses its nutrient arteries. Some well-known abnormalities are listed here.

**Abnormalities at the Craniocervical Junction** Of these, congenital fusion of the atlas and foramen magnum is the most common. McCrae, who described the radiologic features of more than 100 patients with bony abnormalities at the craniocervical junction, found a partial or complete bony union of the atlas and foramen magnum in 28 cases. He noted also that whenever the anteroposterior diameter of the canal behind the odontoid process was less than 19 mm, there were signs of spinal cord compression. Fusion of the second and third cervical vertebrae is a common associated anomaly but does not seem to be of clinical significance.

**Abnormalities of the Odontoid Process** These were found in 17 cases of McCrae’s series. There may be complete separation of the odontoid from the axis or chronic atlantoaxial dislocation (atlas displaced anteriorly in relation to the axis). These abnormalities may be congenital or the result of injury and are known causes of acute or chronic spinal cord compression and stiffness of the neck.

In all the congenital anomalies of the foramen magnum and the upper cervical spine there is a high incidence of syringomyelia (see pages 115 and 1084). McCrae found that 38 percent of all patients with syringomyelia and syringobulbia showed such bony anomalies. All patients whose symptoms might be explained by a lesion in the cervicocranial region (particularly patients in whom MS and foramen magnum tumor are suspected) require careful radiologic examination.

In mucopolysaccharidosis IV, or the Morquio syndrome (page 823), a typical feature is the absence or severe hypoplasia of the odontoid process. This abnormality, combined with laxity or redundancy of the surrounding ligaments, results in atlantoaxial subluxation and compression of the spinal cord. Affected children refuse to walk or develop spastic weakness of the limbs. Early in life they excrete an excess of keratan sulfate, but this may no longer be detectable in adult life. In certain of the mucopolysaccharidoses, we have also seen a true pachymeningiopathy—great thickening of the dura in the basal cisterns and high cervical region with spinal cord compression. Surgical decompression and spinal immobilization has been curative.

**Achondroplasia** This dominantly inherited form of dwarfism is due to a mutation in one of the fibroblastic growth factors, which
causes a failure of conversion of fetal cartilage to bone at the growth plate. It occasionally results in great thickening of the vertebral bodies, neural arches, laminae, and pedicles because of increased periosteal bone formation. The spinal canal is narrowed in the thoracolumbar region, often with kyphosis, leading sometimes to a progressive spinal cord or cauda equina syndrome. Another neurologic complication, which results from a small foramen magnum, is hydrocephalus (internal, with large ventricles, or external, with widened subarachnoid spaces). In young children, a syndrome of central apnea and spasticity of the legs is characteristic. These complications may require ventricular shunting. Narrowing of the lumbar canal tends to present later in life.

**Platybasia and Basilar Invagination**  
Platybasia refers to a flattening of the base of the skull (the angle formed by intersection of the plane of the clivus and the plane of the anterior fossa is greater than 135 degrees). *Basilar impression or invagination* has a somewhat different meaning—namely, an upward bulging of the occipital condyles; if the condyles, which bear the thrust of the spine, are displaced above the plane of the foramen magnum, basilar invagination is present. Each of these abnormalities may be congenital or acquired (as in Paget disease); frequently they are combined. They give rise to a characteristic shortening of the neck and a combination of cerebellar and spinal signs. A normal-pressure hydrocephalus may also develop.

In the *Klippel-Feil syndrome* there is fusion of the upper cervical vertebrae or of the atlas to the occiput. The anomaly is easily identified by substantial foreshortening of the neck. There may be compression of the cervical cord after minor trauma.

**Tethered Cord**  
This developmental anomaly is discussed fully in Chap. 38. A progressive cauda equina syndrome with prominent urinary difficulties, and varying degrees of spasticity are the usual presentations.

**Syphilitic Meningomyelitis**

Here, as in MS, the degree of ataxia and spastic weakness is variable. A few patients have an almost pure state of spastic weakness of the legs, requiring differentiation from motor system disease and familial spastic paraplegia. Such a syndrome, formerly called Erb’s spastic paraplegia and attributed to meningoovascular syphilis, is now recognized as being nonspecific and more often due to demyelinating disease. In a minority of chronic syphilitic patients, sensory ataxia and other posterior column signs predominate. Ventral roots are involved in the chronic meningeal inflammation, giving rise to signs of segmental amyotrophy. Hence the term *syphilitic amyotrophy* of the upper extremities with spastic paraplegia. Confirmation of this now infrequent diagnosis depends on finding a lymphocytic pleocytosis, an elevated protein and gamma globulin, and a positive serologic reaction in the CSF. Other aspects of this disease and treatment are discussed on page 618.

**Subacute Combined Degeneration of the Spinal Cord (SCD; see also Chap. 41, page 992)**

This classic form of nutritional spinal cord disease is due to vitamin B₁₂ deficiency and is fully described on pages 992 to 996. Almost invariably it begins with bilateral symptoms and signs of posterior column involvement in the hands (paresthesias and reduced touch, pressure and joint sensibility), which, if untreated, is followed within a matter of several weeks or months by progressive spastic paraparesis due to involvement of the corticospinal tracts to which a vague sensory level on the trunk may be added. Of particular importance is the fact that SCD is a treatable disease and that the degree of reversibility is dependent upon the duration of symptoms before specific treatment is begun.

**Combined System Disease of Nonpernicious Anemia Type and Hypocupric Myelopathy**

This refers to an intrinsic degenerative disease of the spinal cord, probably somewhat more common than SCD and affecting the posterior and lateral columns (in this sense, also a combined system disease). There is no association with vitamin B₁₂ or folate deficiency, but low serum copper and ceruloplasmin levels are found in some cases and replacement of copper results in stabilization of the illness (Kumar et al). Posterior column signs and gait ataxia are said to predominate. The problem seems to be one of absorption of copper, for example, after bowel surgery, and there may be an anemia. In a recent case on our service, without explanation for the discovered copper deficiency, MRI of the cervical cord revealed distinctive signal changes in both the posterior and lateral columns. It is doubtful that copper depletion accounts for all cases of combined system disease that are not linked to B₁₂ deficiency, but the resemblance of the clinical syndromes is remarkable. Other cases unrelated to B₁₂, or to copper deficiency display predominantly corticospinal signs and are of unknown cause. Little is known of its pathologic basis and perhaps it is a manifestation of several processes.

Progressive spastic or spastic-ataxic paraparesis of a chronic, irreversible type may also develop in conjunction with chronic, decompensated liver disease (page 967); with AIDS; in certain cases of adrenoleukodystrophy, particularly in the symptomatic heterozygote, i.e., the female carrier (page 837); in tropical spastic paraplegia (HTLV-I); in radiation myelopathy; and in adhesive spinal arachnoiditis, which is discussed later.

**Spinal Arachnoiditis (Chronic Adhesive Arachnoiditis)**

This is now a relatively uncommon spinal cord disorder that was introduced in relation to the subject of low back pain (page 180). It is characterized clinically by a combination of painful root and spinal cord symptoms that may mimic intraspinal tumor. Pathologically there is opacification and thickening of the arachnoidal membranes and adhesions between the arachnoid and dura—the result of proliferation of connective tissue. The subarachnoid space is unevenly obliterated. In this sense, the term *arachnoiditis* is not entirely appropriate, although it seems likely that the connective tissue overgrowth is a reaction to an antecedent arachnoidal inflammation. Some forms of arachnoiditis can be traced to syphilis or to a subacutte, therapeutically resistant meningitis of another type. Most others have followed the introduction of a variety of substances, most no longer used, into the subarachnoid space for diagnostic or therapeutic purposes. These included penicillin and other antibiotics, methylene blue, iophendylate (Pantopaque), and other contrast media and corticosteroids. At one time, many examples of adhesive arachnoiditis were observed following spinal anesthesia, occurring soon afterward or after an interval of weeks, months, or even years. Our colleagues observed more than 40 such cases. This complication was eventually traced to a detergent that had contaminated vials of procaine. If enough of the contaminant
was injected, an areflexic paralysis of the legs and sphincters of bladder and bowel and sensory loss in the legs developed within a few days, along with considerable pain. More pernicious, however, was a delayed meningealopathy that developed within a few months or years, causing a spastic paralysis, sensory loss, and incontinence of sphincters. There are cases on record in which an epidural or similar catheter has accidentally penetrated the cord and caused a traumatic partial myelopathy (page 1057). Still seen is a restricted form of arachnoiditis that complicates a series of operations for lumbar discs or the spinal injection of methylene blue. Less convincing are cases attributed to closed spinal injuries. In many cases no provocative factor can be recognized. A familial form has been reported by Duke and Hashimoto, but we have had no experience with it.

Clinical Manifestations  Symptoms may occur in close temporal relation to an acute arachnoidal inflammation or may be delayed for weeks, months, or even years. The most common mode of onset is with pain in the distribution of one or more sensory nerve roots, first on one side, then on both, in the lumbofemoral regions. The pain has a burning, stinging, or aching quality and is persistent. Abnormalities of tendon reflexes are common, but weakness and atrophy, the results of damage to anterior roots, are less frequent findings and tend to occur in cases involving the cauda equina. In thoracic lesions, symptoms of root involvement may antedate those of cord compression by months or years. Sooner or later, however, there is involvement of the spinal cord, manifest by a slowly progressive spastic ataxia with sphincter disturbances.

The localized lumbar arachnoiditis associated with repeated disc surgery (the common variety seen in pain clinics) is characterized by back and or leg pain with other inconstant signs of radiculopathy (loss of tendon reflexes, weakness, and variable degrees of sensory loss), usually bilateral.

The CSF is abnormal during the acute stage in practically all cases of adhesive arachnoiditis. In some there is a moderate lymphocytic pleocytosis, occurring soon after the inciting event, but the striking finding is a partial or complete obliteration of the spinal subarachnoid space, sometimes extreme in degree. In the localized lumbar arachnoiditis, referred to earlier, the CSF may be normal or show only a slight increase in protein content. The localized myelographic appearance of arachnoiditis is characteristic (patchy dispersion of the column of dye and a "candle-guttering" appearance that was most evident with oil-based contrast media); MRI reveals a loss of the normal ring of CSF or localized loculations of CSF (see Fig. 11-6). These ancillary procedures and the CSF formula, if obtained in the acute stages, allow one to make the diagnosis with certainty. Later, the CSF shows only an elevated protein content.

Pathologic Features  In advanced cases the subarachnoid space is completely obliterated and the roots and cord are strangulated by the thickened connective tissue. Subpial nerve fibers of the cord are destroyed to a varying extent, and peripherally placed fibers of the posterior and lateral columns undergo secondary degeneration. Where the pathologic process is confined to relatively circumscribed portions of the cord, the subarachnoid space may be occupied by loculated collections of yellowish, high-protein fluid (meningitis serosa circumscripta). The rare association of spinal arachnoiditis and syringomyelic cavitation of the cord is considered further on in this chapter.

Treatment  In the early stages of arachnoiditis, corticosteroids have been given systematically to control the inflammatory reaction and to prevent progress of the disease, but their value is question-
(1) those that arise within the substance of the spinal cord, either as a primary neural neoplasm or as a metastasis, and invade and destroy tracts and central gray structures (intramedullary) and (2) those arising outside the spinal cord (extramedullary), either from vertebral bodies and epidural tissues (extradural) or in the leptomeninges or roots (intradural). In a general hospital, the relative frequency of spinal tumors in these different locations is about 5 percent intramedullary, 40 percent intradural-extradural, and 55 percent extradural, the majority of the latter being metastatic cancers, as already mentioned. This percentage of extradural lesions is higher than that encountered in more specialized neurosurgical services (e.g., Elsberg’s figures of 7, 64, and 29 percent, respectively), probably because the latter do not include as many patients with extradural lymphomas, metastatic carcinomas, etc., as are seen in general hospitals.

The most common primary extradural tumors are the neurofibromas and meningiomas (Fig. 44-10), which together constitute about 55 percent of all intraspinal neoplasms. They are more often intradural than extradural. Neurofibromas have a predilection for the thoracic region, whereas meningiomas are more evenly distributed over the vertical extent of the cord. The other primary extradural tumors are sarcomas, vascular tumors, chordomas, and epidermoid and similar tumors, in that order of frequency.

Primary intramedullary tumors of the spinal cord have the same cellular origins as those arising in the brain (Chap. 31), although the proportions of particular cell types differ. Ependymomas (some of which arise from the filum terminale; page 860) make up 60 percent of the spinal cord cases (Fig. 44-11) and astrocytomas about 25 percent. The astrocytoma is the most common intramedullary tumor if one excludes tumors arising in the filum terminale. Oligodendrogliomas are much less common. The remainder (about 10 percent) consists of a diverse group of nongliomatous tumors: lipomas, epidermoids, dermoids, teratomas, hemangiomas, hemangioblastomas, and metastatic carcinomas. The cavernous hemangioma may be a source of spontaneous hematomyelia. As indicated further on, there is a frequent association between intramedullary tumors (both gliomatous and nongliomatous) and syringomyelia. The basis of this relationship remains obscure.

Intramedullary growths invade as well as compress and distort fasciculi in the spinal cord white matter. As the cord enlarges from the tumor growing within it or is compressed by a tumor from without, the free space around the cord is eventuallly consumed, and the CSF below the lesion becomes isolated or loculated from the remainder of the circulating fluid above the lesion. This is indicated by a Froin syndrome (xanthochromia and clotting of CSF) and an interruption of flow of contrast medium in the subarachnoid space (by myelogram). The most informative diagnostic procedure
is an MRI, which demonstrates both the intramedullary extent of the tumor and the effect on the surrounding subarachnoid space.

Secondary spinal cord tumors can also be subdivided into intramedullary and extramedullary types. Extramedullary metastases (carcinoma, lymphoma, myeloma) are the most common of all spinal tumors. They account for the largest group of patients who develop symptoms of myelopathy while being cared for in hospital and are therefore likely to be encountered in the course of providing neurologic consultations. Extramedullary metastases arise from hematogenous deposits or extend from tumors of the vertebral bodies or from a paraspinal tumor extending via the intervertebral foramina (Fig. 44-12). Secondary extramedullary tumor growths are far more often extradural than intradural. The intradural type takes the form of a meningeal carcinomatosis or lymphomatosis and the rare primary melanoma of the meninges, which is considered in Chap. 31.

Intramedullary metastases are not as rare as is generally believed. In a retrospective autopsy study of 627 patients with systemic cancer, Costigan and Winkelmann found 153 cases with CNS metastases, in 13 of which the metastases were located within the cord. In 9 of the 13 cases, the metastasis was deep in the cord, unassociated with leptomeningeal carcinomatosis; in 4 cases, the neoplasm seemed to extend from the pia. Bronchogenic carcinoma was the main source. Diagnosis is difficult but is aided greatly by MRI with gadolinium infusion; there is generally extensive contiguous edema (Fig. 44-13). Differentiation is from meningeal carcinomatosis, radiation myelopathy, and paraneoplastic necrotizing myelopathy, which is the rarest of these entities. Treatment is usually ineffective unless radiation therapy is begun before paraplegia supervenes (Winkelmann et al).

Symptomatology Patients with spinal cord tumors are likely to present with one of three clinical syndromes: (1) a sensorimotor spinal tract syndrome, (2) a painful radicular-spinal cord syndrome, or (3) least often, an intramedullary syringomyelic syndrome. The sensory features of these syndromes are shown in Fig. 9-5 on page 140.

Pain and stiffness of the back may antedate signs of spinal cord disease or dominate the clinical picture in some cases of extramedullary tumors. The back pain is usually worse when the patient lies down or may become worse after several hours in the recumbent position and be improved by sitting up. In children, severe back pain associated with spasm of paravertebral muscles is often prominent initially; scoliosis and spastic weakness of the legs come later. Because of this somewhat unusual clinical presentation and the rarity of intraspinal lesions in childhood, spinal cord tumors in this age group may be overlooked.

Sensorimotor Spinal Tract Syndrome The clinical picture is related predominantly to compression and less often to invasion and destruction of spinal cord tracts. The signs of compression consist of (1) an asymmetrical spastic weakness of the legs with thoracolumbar lesions and of the arms and legs with cervical lesions, (2) a sensory level on the trunk below which perception of pain and temperature is reduced or lost, (3) posterior column signs, and (4) a spastic bladder under weak voluntary control. The onset of the compressive symptoms is usually gradual and the course progressive over a period of weeks and months, frequently with back pain. With extradural tumors, paralysis usually develops over a period of days to several weeks, but the tempo of progression may be more rapid or more leisurely. The initial disturbance may be motor or sensory and the distribution asymmetrical. High cervical or foramen magnum lesions produce special clinical syndromes, as discussed on page 52 and below. With thoracic lesions, one leg usually becomes weak and stiff before the other one. Subjective sensory symptoms of the dorsal column type (tingling paresthesias) assume similar patterns. Pain and thermal senses are more likely to be affected than tactile, vibration, and position senses. Nevertheless, the posterior columns are frequently involved. Initially the sensory disturbance is contralateral to the maximum motor weakness, but a sharply defined Brown-Séquard hemisindrome is rarely observed. The bladder and bowel usually become paralyzed coincident with paralysis of the legs. If the compression is relieved, there is recovery from these sensory and motor symptoms, often in the reverse order of their appearance; the first part affected is the last to recover, and sensory symptoms tend to disappear before motor ones.

Radicular-Spinal Cord Syndrome Here the syndrome of spinal cord compression is combined with radicular pain, i.e., pain in the distribution of a sensory nerve root. It is described as knife-like or as a dull ache with superimposed sharp stabs of pain, which radiate in a distal direction, i.e., away from the spine, and are intensified by coughing, sneezing, or straining. Segmental sensory changes (paresthesias, impaired perception of pinprick and touch) and/or motor disturbances (cramp, atrophy, fascicular twitching, and loss of tendon reflexes) and an ache in the spine, in addition to the radicular pain, are the usual manifestations. Tenderness of spinous
processes over the growth is found by percussion in about half the patients. The segmental changes, particularly the sensory radicular ones, often precede the signs of spinal cord compression by months if the lesion is benign.

**Intramedullary Syringomyelic Syndrome** No single symptom is unique to intramedullary tumors. Some degree of pain, sometimes minor, is common and is almost invariably present with tumors of the filum terminale. Ependymomas and astrocytomas, the two most common intramedullary tumors, usually give rise to a mixed sensorimotor tract syndrome. When the intramedullary tumor involves the central gray matter, a central cord, or syringomyelic syndrome may result (page 1084). The main features are segmental or dissociated sensory loss, atrophy, early incontinence, and late corticospinal weakness. Also, on sensory examination, sacral sparing may be found but is of less value in distinguishing intramedullary from extramedullary lesions. A dissociation of thermal pain and tactile sensory loss over several segments on the trunk is a more dependable sign of an intramedullary lesion. Rarely, an extramedullary tumor may give rise to a syringomyelic syndrome, possibly by causing vascular insufficiency in the central portion of the cord.

**Special Spinal Syndromes** Unusual clinical syndromes may be found in patients with tumors in the region of the foramen magnum. They produce a quadriplegia with pain in the back of the head and stiff neck, weakness and atrophy of the hands and dorsal neck muscles, marked imbalance, and variable sensory changes—or, if they spread intracranially, there may be signs of cerebellar and lower cranial nerve involvement. As noted earlier and in Chap. 3, slowly growing tumors in this region, such as meningiomas, characteristically produce an “around the clock” progression of weakness beginning in one limb and proceeding to the adjacent one. Lesions at the level of the lowermost thoracic and the first lumbar vertebrae may result in mixed cauda equina and spinal cord symptoms. A Babinski sign indicates that the spinal cord is involved above the fifth lumbar segment. Lesions of the cauda equina alone, always difficult to separate from those of the lumbosacral plexuses and multiple nerves, are usually attended in the early stages by sciatic and other root pain and lumbar ache, which is variously combined with a bilaterally asymmetrical, atrophic, areflexic paralysis, radi- cular sensory loss, and sphincteric disorder. These must be dis- tinguished from lesions of the conus medullaris (lower sacral segments of the spinal cord), in which there are early disturbances of the bladder and bowel (urinary retention and constipation), back pain, symmetrical hypalgesia or anesthesia over the sacral dermatomes, a lax anal sphincter with loss of anal and bulbocavernous reflexes, impotence, and sometimes weakness of leg muscles. Sensory abnormalities may precede motor and reflex changes by many months. Very rarely, for unclear reasons, tumors of the thoracicolumbar cord (intramedullary, as a rule) may be associated with markedly elevated spinal fluid protein and hydrocephalus; these respond to shunting and removal of the spinal tumor (Feldman et al). Less often, these tumors have caused a pseudotumor cerebri syndrome.

**Differential Diagnosis** Several problems arise in the diagnosis of spinal cord tumors in addition to those previously mentioned. In their early stages they must be distinguished from other diseases that cause pain over certain segments of the body, i.e., diseases affecting the gallbladder, pancreas, kidney, stomach and intestinal tract, pleura, etc. Localization of the pain to a dermatome; its intensification by sneezing, coughing, and straining, and sometimes by recumbency; and the finding of segmental sensory changes and minor alterations of motor, reflex, or sensory function in the legs will usually provide the clues to the presence of a spinal cord-radicular lesion. MRI will settle the diagnosis in most instances.

There is then the problem of locating the segmental level of the lesion. At first, the sensory and motor deficits may be most pronounced in those parts of the body farthest removed from the lesion, i.e., in the feet or lumbosacral segments. Later the levels of the sensory and motor deficits ascend, but they may still be at a level several segments below the lesion. In determining the level of the lesion, the location of back pain, root pain, and atrophic paralysis are of greater help than the upper level of hypalgesia.

Once vertebral and segmental levels of the lesion are settled, there remains the necessity of determining whether the lesion is extradural, intradural-extradural, or intramedullary and whether it is neoplastic. If there is a visible or palpable spinal deformity or radiographic evidence of vertebral destruction, one may confidently assume an extradural localization. Even without these changes, one still suspects an extradural lesion if root pain developed early and is bilateral, if pain and aching in the spine are prom-
inent and percussion tenderness is marked, if motor symptoms below the lesion preceded sensory ones, and if sphincter disturbances were late. However, to distinguish between intradural-extradural lesions and intramedullary lesions on clinical grounds alone is often difficult. The findings of segmental amyotrophy and sensory loss of dissociated type (loss of pain and temperature and preservation of tactile sensation) point to an intramedullary lesion.

Extradural tumors, both primary and secondary, must be differentiated from cervical spondylosis, tuberculous granuloma, sarcoidosis, arteriovenous malformations of the cord, spinal dural fistulas, and certain chronic pyogenic or fungal granulomatous lesions, from lipomas in patients receiving corticosteroids for prolonged periods, and from the necrotizing myelopathy associated with occult tumors or occurring independently of them. In the thoracic region, a ruptured disc or evagination of the cord through a dural tear is always a possibility. In the region of the lower back, i.e., over the cauda equina, one must also distinguish between tumor and protruded intervertebral disc. Here, an extradural tumor may produce mainly sciatic and low back pain with little or no motor, sensory, reflex, or sphincteric disturbances. With intradural-extradural lesions, the important diagnostic considerations are meningioma, neurofibroma, meningeal carcinomatosis, cholesteatoma, and teratomatous cyst, a meningo(myel)itic process, or adhesive arachnoiditis. The cytologic study of cells in the CSF and the use of MRI are the essential laboratory aids. Intramedullary lesions are usually gliomas, ependymomas, or vascular malformations or, in the context of a known carcinoma, intramedullary metastases. The definition of vascular malformations by means of selective spinal angiography has been discussed in an earlier section of this chapter. Normal protein in the CSF and negative MRI effectively exclude intramedullary tumors and granulomatous lesions.

**Treatment** Treatment depends on the nature of the lesion and the clinical condition of the patient.

The main consideration in the management of epidural metastases is the need for early diagnosis, at a stage when only back pain is present and before neurologic symptoms and signs have appeared. Once neurologic signs appear, the results of treatment are poor. Epidural growths of carcinoma and lymphoma are best managed by the administration of radiation to the region of tumor involvement, endocrine therapy (for carcinoma of breast and prostate), the administration of antineoplastic drugs (for certain lymphomas and myelomas), and the early use of high-dose steroids and analgesics for pain. Seldom is operation necessary as a first resort. Gilbert and his associates have presented evidence that patients who receive high-dose corticosteroids (16 to 60 mg of dexamethasone) and fractionated radiation (500 cGy on each of the first 3 days and then spaced radiation up to 3000 cGy) do as well as surgically treated patients. Sometimes laminectomy and decompression are necessary for diagnosis and, with a rapidly growing tumor, to prevent irreversible compressive effects and infarction of the spinal cord. Cases that have been allowed to progress should probably be operated on if paraplegia has just occurred. If the maximal safe radiation dosage had previously been applied to the spinal column, surgical palliation is usually undertaken.

Intradural-extradural tumors should generally be removed if this can be accomplished safely, and this applies to benign extradural tumors that are symptomatic as well. Laminectomy, decompression, excision in isolated cases, and radiotherapy constitute the treatment of intramedullary gliomas. Such patients may improve and lead useful lives for a decade or longer. Constantini and colleagues, based on their experience with 164 instances of intramedullary lesions, mainly gliomas, in children and young adults, recommend a radical excision of the tumor, but this approach has not been subjected to a trial.

**Other Rare Causes of Spinal Cord Compression**

Epidural fat deposition with spinal cord or cauda equina compression occurs in Cushing disease and after the long-term use of corticosteroids but also in the absence of these disorders. The clinical picture may suggest discogenic disease (Lipson et al). Copious amounts of normal adipose tissue are found at laminectomy, and removal of this tissue is curative. Lowering the dose of steroid and caloric restriction will help mobilize the fat and relieve the symptoms. (An intraspinal lipoma is also a component of the developmentally tethered cord, but in this process the essential problem is a conus medullaris myelopathy from stretching of the cord, rather than compression; see Thomas and Miller.)

*Arachnoid diverticula*—intra- or extradural outpouchings from the posterior nerve root—are rare causes of a radicular-spinal cord syndrome first described by Bechterew in 1893. They tend to occur in the thoracic or lumbosacral regions. The symptoms, in order of decreasing frequency, are pain, radicular weakness and sensory disorder, gait disorder, and sphincteric disturbances (Ciluffo et al). The frequent association of arachnoid diverticula with osteoporosis, ankylosing spondylitis, and arachnoiditis makes it difficult to interpret the role of the diverticula themselves. Surgical obliteration of the pouches has yielded unpredictable results. They have attained clinical importance more often in our experience as the source of spontaneous CSF leaks and a low-pressure syndrome (Chap 30).

Spinal cord compression with paraplegia may be caused by *extramedullary hemato poiesis* in cases of myelosclerosis, thalassemia, cyanotic heart disease, myelogenous leukemia, sideropenic anemia, and polycythemia vera (Oustwani et al). A similar phenomenon occurs with ossification of the posterior longitudinal ligament, as described earlier.

Solitary *osteochondromas* of vertebral bodies and multiple *exostoses* of hereditary type are other reported causes of spinal cord compression. In the case reported by Buur and Morch, the clinical syndrome was one of pure spastic paraparesis of several months' progression.

**Lathyrism** (See also page 1033)

From the interesting historical review of Dastur, one learns that this disease was known to Hippocrates, Pliny, and Galen in Europe, to Avicenna in the Middle East, and to the ancient Hindus. The term *lathyrism* was applied by Cantani, in Italy, because of its recognized relationship to the prolonged consumption of *Lathyrus sativus* (chickling vetch, vetch pea, or grass pea).

The disease is still common in some parts of India and Africa. In these districts, during periods of famine when wheat and other grains are in short supply, the diet may for months consist of flour made of the grass pea. In individuals so exposed there occurs a gradual weakening of the legs accompanied by spasticity and cramps. Paresthesias, numbness, formation in the legs, and frequency and urgency of micturition, impotence, and sphincteric
spasms are added. The upper extremities may exhibit coarse tremors and involuntary movements. These symptoms, once established, are more or less permanent but not constantly progressive, and most of the patients live out their natural life span.

Only two reports on the neuropathology of lathyrism were known to Dastur, one by Buzzard and Greenfield in England, the other by Filiminoff in Russia. Both of their patients had been in a stationary paraplegic state for years. Greenfield noted a loss of ascending and descending tracts in the spinal cord, particularly the corticospinal and direct spinocerebellar tracts. Filiminoff observed a loss of myelinated fibers in the lateral and posterior columns. Unlike the cases of Spencer et al, there had been a loss of pain and thermal sensation in the upper extremities. The larger Betz cells had disappeared, while anterior horn cells were unaffected. Gliosis and thickening of blood vessels was seen in the degenerated tracts.

The toxic nature of this disease, long suspected, was confirmed by Spencer and colleagues. They extracted a neuroexcitatory amino acid, beta-N-oxalylaminolanoalanine (BOAA), from grass peas and were able to induce corticospinal dysfunction in monkeys by giving this substance with a nutritious diet. Subsequently, Hugon and coworkers produced a primate model of lathyrism by feeding monkeys a diet of _L. sativus_ in addition to an alcoholic extract of this legume. These findings tend to negate the importance of several other factors that until now had been thought to be causative—namely, malnutrition, ergot contamination, and toxins derived from _Vicia sativa_, the common vetch that grows alongside the lathyrus species.

The African acute spastic paraplegia called “konzo” has a similar toxic pathogenesis; it is caused by cyanide-like compounds in flour made from cassava.

**Dysraphic Syndromes (Spina Bifida) and Tethered Cord**

These are described in Chap. 38.

**Familial Spastic Paraplegia** (See Chap. 39 and Table 39-8)

There are several familial forms of progressive spastic paraplegia, some beginning in childhood, others in adult life. The pattern of inheritance in almost all our adult cases has been autosomal dominant. A lack of sensory symptoms and signs and sparing of sphincteric function until late in the illness are important diagnostic features. A number of adult cases are “complicated” in the sense that the spastic paraplegia is associated with cerebellar ataxia or dementia. By contrast, _primary lateral sclerosis_, a sporadic form of degenerative disease of the motor system, is characterized by a pure spastic paraplegia and bulbar spastic palsy either initially or with progression, the result of changes that are confined to the corticospinal pathways. These disorders are discussed extensively with the heredodegenerative diseases in Chap. 39, and the myelopathy associated with adrenoleukodystrophy, in Chap. 37.

**SYRINGOMYELIC SYNDROME OF SEGMENTAL SENSORY DISSOCIATION WITH BRACHIAL AMYOTROPHY**

This syndrome is most often attributable to developmental syringomyelia, i.e., a central cavitation of the spinal cord of undetermined cause, but a similar clinical syndrome may be observed in association with other pathologic states such as intramedullary cord tumors, traumatic myelopathy, postradiation myelopathy, infarction (myelomalacia), bleeding (hematomyelia), and rarely with extramedullary tumors, cervical spondylisis, spinal arachnoiditis, and cervical necrotizing myelitis.

**Syringomyelia (Syrinx; see also Chap. 38)**

Syringomyelia (from the Greek _syrinx_, “pipe” or “tube”) is defined as a chronic progressive degenerative or developmental disorder of the spinal cord, characterized clinically by painless weakness and wasting of the hands and arms (brachial amyotrophy) and segmental sensory loss of dissociated type (loss of thermal and painful sensation with sparing of tactile, joint position, and vibratory sense, as described later). Pathologically there is cavitation of the central parts of the spinal cord, usually in the cervical region, but extending upward in some cases into the medulla oblongata and pons (syringobulbia) or downward into the thoracic or even the lumbar segments. Frequently there are associated developmental abnormalities of the vertebral column (thoracic scoliosis, fusion of vertebrae, or Klippel-Feil anomaly), of the base of the skull (platybasia and basilar invagination), and particularly of the cerebellum and brainstem (type I Chiari malformation). Approximately 90 percent of cases of syringomyelia have type I Chiari malformation consisting of a descent of cerebellar tonsils (see page 861). Conversely, approximately 50 percent of type I Chiari malformations are associated with syringomyelia. There is also a group of less frequent but well-described syringomyelia that derives from the acquired processes mentioned earlier such as intramedullary tumor (astrocytoma, hemangioblastoma, ependymoma) and traumatic or hemorrhagic necrosis of the spinal cord.

Wider experience with the pathology of the developmental type of syringomyelia and better understanding of the postulated mechanisms have led to the following classification, modified from Barnett and colleagues:

- **Type I.** Syringomyelia with obstruction of the foramen magnum and dilation of the central canal (developmental type)
  - A. With type I Chiari malformation
  - B. With other obstructive lesions of the foramen magnum

- **Type II.** Syringomyelia without obstruction of the foramen magnum (idiopathic developmental type)

- **Type III.** Syringomyelia with other diseases of the spinal cord (acquired types)
  - A. Spinal cord tumors (usually intramedullary, especially hemangioblastoma)
  - B. Traumatic myelopathy
  - C. Spinal arachnoiditis and pachymeningitis
  - D. Secondary myelomalacia from cord compression (tumor, spondylosis), infarction, hematomyelia

- **Type IV.** Pure hydromyelia (developmental dilatation of the central canal), with or without hydrocephalus

**Historical Note** Although pathologic cavitation of the spinal cord was recognized as early as the sixteenth century, the term _syringomyelia_ was first used to describe this process in 1827 by Olivier d’Angers (cited by Ballantine et al). Later, following recognition of the central canal as a normal structure, it was assumed by Vir-
chow (1863) and by Leyden (1876) that cavitation of the spinal cord had its origin in an abnormal expansion of the central canal, and they renamed the process hydromyelia. Cavities in the central portions of the spinal cord, unconnected with the central canal, were recognized by Hallopeau (1870); Simon suggested in 1875 that the term syringomyelia be reserved for such cavities and that the term hydromyelia be restricted to simple dilatation of the central canal. Thus, a century ago, the stage was set for an argument about pathogenesis that has not been settled to the present day.

Clinical Features The clinical picture varies in the four pathologic types previously listed, the differences depending not only on the extent of the syrinx but also on the associated pathologic changes, particularly those related to the Chiari malformation. In the classic type I syrinx (idiopathic and Chiari developmental syringomyelia) symptoms usually begin in early adult life (20 to 40 years). Males and females are equally affected. Rarely, some abnormality is noted at birth, but usually the first symptom appears in late childhood or adolescence. The onset is usually insidious and the course irregularly progressive. In many instances the symptoms or signs are discovered accidentally, for example as a result of painless burn or atrophy of the hand, and the patient cannot say when the disease began. Rarely, there is an almost apoplectic onset or worsening; there are cases on record of an aggravation of old symptoms or the appearance of new symptoms after a violent strain or paroxysm of coughing. Trauma is a less certain precipitant. Once the disease is recognized, some patients remain much the same for years, even decades, but more often there is intermittent progression to the point of being chairbound within 5 to 20 years. This extremely variable course makes it difficult to evaluate therapy.

The precise clinical picture at any given point in the evolution of the disease depends on the cross-sectional and longitudinal extent of the syrinx, but certain clinical features are so common that the diagnosis can hardly be made without them. These classic elements are: (a) segmental weakness and atrophy of the hands and arms, (b) loss of some or all tendon reflexes in the arms, and (c) segmental anesthesia of a dissociated type (loss of pain and thermal sense and preservation of the sense of touch) over the neck, shoulders, and arms. The last of these leads to one of the most characteristic features of syringomyelia, painless injuries and burns of the hands. Finally, there are in cases of extensive cavitation, weakness and ataxia of the legs from involvement of the corticospinal tracts (possibly at their decussation) and posterior columns in the cervical region. Kyphoscoliosis is added in many of the cases and in nearly one-quarter of them there is an overt cervico-occipital malformation (short neck, low hairline, odd posture of the head and neck, fused or missing cervical vertebrae i.e., Klippel-Feil abnormality).

The particular muscle groups that are affected on the two sides may vary. Exceptionally, motor function is spared, and the segmental dissociated sensory loss and/or pain are the only marks of the disease. In a few of the cases, especially those with the Chiari malformation, the reflexes in the arms are preserved or even hyperactive, as might be expected with upper rather than lower motor neuron involvement. Or the shoulder muscles may be atrophic and the hands spastic. In the lower extremities the weakness, if present, is of a spastic (corticospinal) type.

The characteristic segmental sensory dissociation is usually bilateral, but a unilateral pattern affecting only one hand and arm is not unknown, and this is true of the amyotrophy as well. The sensory loss is distributed in a “cape” or hemisphere pattern, often extending to back of the head or the face and onto the trunk. Although tactile sensation is usually preserved, there are cases in which it is impaired, usually in the region of the densest analgesia. Exceptionally there is no sensory loss in the presence of amyotrophy, and cases have been recorded in which only a hydrocephalus and hydromyelia were present with spastic paraparesis. If tactile sensation is affected in the arms, joint position and vibratory sense tend also to be impaired. In the lower extremities there may be some loss of pain and thermal sensation proximally and over the abdomen, but more often there is a loss of vibratory and position sense which is indicative of a posterior column lesion and is the basis of ataxia. A Horner syndrome may result from ipsilateral involvement of the intermediolateral cell column at the C8, T1, and T2 levels.

Pain has been a symptom in about half of our patients with developmental types I and II syringomyelia. The pain is usually unilateral or more marked on one side of the neck, shoulder, and arm; it is of a burning, aching quality, mostly in or at the border of areas of sensory impairment. In a few patients it involves the face or trunk. An aching pain at the base of the skull or posterior cervical region—intensified by coughing, sneezing, or stooping (brief exertional pain)—is often present. But, as Logue and Edwards point out, pain of this type may be a feature of Chiari malformation without syringomyelia and in that case is probably attributable to compression or stretching of cervical roots.

Syringobulbia is the lower brainstem equivalent of syringomyelia. Usually the two coexist and the brainstem cavity is an extension of one in the upper cord, but occasionally the bulbar manifestations precede the spinal ones or, rarely, occur independently. The glial cleft or cavity is located most often in the lateral tegmentum of the medulla, but it may extend into the pons and, rarely, even higher. The symptoms and signs are characteristically unilateral and consist of nystagmus, analgesia, and thermoanesthesia of the face (numbness); wasting and weakness of the tongue (dysarthria); and palatal and vocal cord paralysis (dysphagia and hoarseness). Diplopia, episodic vertigo, trigeminal pain or facial sensory loss, and persistent hiccup are less common symptoms. For understandable reasons, the diagnosis of brainstem MS is often raised. The clinical and pathologic features of syringobulbia have been described in great detail by Jonesco-Sisesti. A most unusual keyhole-shaped syrinx, which was confined to the upper pons and midbrain and communicated with the fourth ventricle, has been described by de la Monte and colleagues.

When a Chiari malformation is associated with syringomyelia and syringobulbia, it may be difficult to separate the effects of the two disorders. Clinical features that favor the diagnosis of Chiari malformation are nystagmus, cerebellar ataxia, exertional head—neck pain, prominent corticospinal and sensory tract involvement in the lower extremities, hydrocephalus, and craniocervical malformations. In syringomyelia without a Chiari malformation but with some other type of obstructive lesion at the foramen magnum, the clinical picture is much the same, and the nature of the foramen magnum lesion can be determined only by MRI or surgical exploration.

The association of syringomyelia with an intramedullary tumor (type III) should be suspected when there is a syringomyelic type of sensorimotor abnormality extending over many segments of the body. With von Hippel-Lindau disease, the diagnosis hinges on the finding of the characteristic hereditary hemangioblastoma in the syrinx and retinal and cerebellar vascular malformations. In the posttraumatic cases, a necrosis of the spinal cord that has been stable for months or years begins to cause pain and spreading sen-
sory or motor loss, recognizable only in segments above the original lesion (Schurch et al). This occurred in approximately 3 percent of the traumatic myelopathy cases of Rossier and coworkers, more often in quadriplegics than in paraplegics. The posttraumatic syrinx is not as well defined anatomically as the usual forms of syringomyelia but consists instead of several contiguous areas of glia-lined myelomalacia with differing degrees of cavitation. In some instances of progressive spinal cord symptoms occurring several years after spinal surgery, the lesion has proved to be one of arachnoiditis and cord atrophy and not a syrinx (Avrahami et al).

Hydromyelia (Type IV) This refers to a dilation of the central canal and is considered a process distinct from developmental syringomyelia. The relationship between hydromyelia and syringomyelia has been the source of endless debate, in part the result of the lack of a coherent pathophysiologic explanation for either process. At least one hypothesis for the origin of syringomyelia includes an initial dilatation of the central canal (see later). Our impression is that a relatively nonprogressive well-defined cylindrical enlargement of the central canal over a few thoracic segments is a frequent enough occurrence in the absence of other changes that it represents an independent entity. In the few cases of true hydromyelia that have come to our attention there has sometimes been a long-standing congenital hydrocephalus complicated years later by progressive weakness and atrophy of the shoulders and the muscles of the arms and hands. More often, there is no associated obstruction at the upper cord and no hydrocephalus. It is our impression that most cases are benign and relatively nonprogressive. Proof of the existence of pure hydromyelia in the past has been based on necropsy demonstration of an enormously widened central canal, with or without hydrocephalus. Now it is easily diagnosable by MRI, however, numerous asymptomatic cases with mild dilation of the central canal are being discovered and cause unnecessary concern.

Pathogenesis Experimental work in animals indicates that there is a normal flow of CSF from the spinal subarachnoid space, through perivascular spaces, to the parenchyma of the cord and possibly into the central canal. It has been suggested that impediments to flow might then explain dilation of the central canal, but not necessarily the creation of a parallel or attached syrinx cavity.

One theory of the pathogenesis of developmental syringomyelia, of which Gardner was the most persuasive advocate, is that the normal flow of CSF from the central canal to the fourth ventricle and its outlets is prevented by an obstruction of the foramina of Luschka and Magendie. As a result, a pulse wave of CSF pressure, generated by systolic pulsations of the choroid plexuses, is transmitted into the cord from the fourth ventricle through the central canal. According to this theory, the syrinx consists essentially of a greatly dilated central canal with a diverticulum that ramifies from the central canal and dissects along gray matter and adjacent fiber tracts. The frequency with which syringomyelia is linked to malformations at the cranio cervical junction, i.e., to Chiari and other lesions that could interfere with normal flow of CSF, lent credence to this theory.

There are many instances, however, where Gardner’s hydrodynamic theory could not explain the syringomyelia. In some cases, for example, the foraments of Luschka and Magendie are found to be patent, and other abnormalities of the posterior fossa or foramen magnum are also not in evidence. Furthermore, in many cases, including several of our own, serial histologic sections have failed to demonstrate a connection between the fourth ventricle and the syrinx in the spinal cord or a widening of the central canal above the syrinx (see also Hughes).

Gardner’s theory has been questioned on other grounds. Ball and Dayan calculated the pulse-pressure wave transmitted into the cord to be of so low an order as to be unlikely to produce a syrinx. In their view, the CSF around the cervical cord, under increased pressure during strain or physical effort because of subarachnoid obstruction at the cranio cervical junction, tracks into the spinal cord along the Virchow-Robin spaces or other subpial channels as described earlier. Over a prolonged period, abetted perhaps by traumatic lesions, small pools of fluid coalesce to form a syrinx; originally the syrinx forms independently of the central canal, but eventually the two may become connected, allowing secondary enlargement of the canal (hydromyelia ex vacuo). The findings of Heiss and colleagues lend strong support to the theory of Ball and Dayan. According to them, progression of syringomyelia is produced by the compressive effect of the cerebellar tonsils, which partially occlude the subarachnoid space at the foramen magnum and create pressure waves that compress the spinal cord from without and not from within; the pressure waves propagate syrinx fluid caudally with each heartbeat. This hardly exhausts the list of hypotheses, but none of them is easy to confirm, and there is no point in enumerating them all.

The authors favor the type of hydrodynamic mechanism as postulated originally by Gordon Holmes and elaborated by Ball and Dayan. In this view, a relationship exists between basal cranial, cervical spine, the cerebellospinal Chiari malformation, syringomyelia and disturbed hydrodynamics of perispinal CSF. Logue and Edwards have documented several cases of syringomyelia in which the foramen magnum was obstructed by a lesion other than a Chiari formation—dural cyst, localized arachnoiditis, atlantoaxial fusion, simple cerebellar cyst, and basilar invagination (see Williams for a review of the numerous hypotheses of causation).

Irrespective of its mode of origin, the syrinx first occupies the central gray matter of the cervical portion of the spinal cord, usually independent of the central canal but sometimes extending into it. It interrupts the crossing pain and temperature fibers in the anterior commissure at several successive cord segments. As the cavity enlarges, it extends symmetrically or asymmetrically into the posterior and anterior horns and eventually into the lateral and posterior funiculi of the cord. It may enlarge the spinal cord. The cavity is lined with astrocytic glia and a few thick-walled blood vessels, and the fluid in the cavity is clear and in our patients has had a relatively low protein content, like CSF.

The cavitation nearly always arises in the cervical portion of the cord and can only reach the thoracic and lumbar portions by extension from the cervical region. Either a cavity or a glial septum may extend asymmetrically into the medulla, usually in the vicinity of the descending tract of the fifth cranial nerve (syringobulbia).

Diagnosis The clinical picture of syringomyelia is so characteristic that diagnosis is seldom in doubt. Now one can obtain spectacular demonstrations of the syrinx, Chiari malformations, and other foramen magnum lesions by MRI in the sagittal plane of the brain and spinal cord (see Figs. 38–4 and 44–14). Hours after a CT myelogram, contrast material fills the syrinx and the central canal directly, possibly by diffusion from the surface of the cord.

In addition to acquired lesions in the central cord, certain rare polynuropathies (amyloid, Tangier disease, and Fabry disease) that preferentially affect small fibers in the nerves of the upper
extremities can reproduce the dissociated sensory loss that is characteristic of a syrinx (“pseudosyringomyelic” deficit), but syringomyelic motor abnormalities are not found in these neuropathic cases. These diseases are discussed in Chap. 46.

**Treatment** The only therapy of lasting value for type I syringomyelia (related to Chiari malformation) is surgical decompression of the foramen magnum and upper cervical canal. Headache and neck pain are helped most; ataxia and nystagmus tend to persist. Radiation therapy, which was formerly recommended, is of no benefit. The operation advised by Gardner, of plugging the connection between the fourth ventricle and the central canal of the cervical cord, has been abandoned. There were complications of this operative procedure, and the results were no better than those obtained from simple decompression. The decompression operation also carries some risk, especially if there is an attempt to excise the tonsillar projections of the cerebellum. In the series of Logue and Edwards, comprising 56 cases of type I syringomyelia, the occipitocervical pain was relieved by decompression in most patients, but the shoulder-arm pain usually persisted. Upper motor neuron weakness of the legs and sensory ataxia were often improved, whereas the segmental sensory and motor manifestations of the syringomyelia were not. Hankinson has reported good results from decompression in 75 percent of type I cases of syringomyelia. In the retrospective review of 141 adult patients by Stevens and colleagues, good surgical outcome was achieved in 50 percent of those with minor degrees of descent of the cerebellar tonsils but in only 12 percent of those with major cerebellar ectopia. A distended syrinx also led to a more favorable outcome. Whether the long-term course of these diseases is altered has not been determined.

Syringostomy or shunting of the cavity has been performed in type I and some of the type II (idiopathic) cases, but the results have been unpredictable. Love and Olafson, who performed this procedure in 40 patients of both types (mainly type II), stated that 30 percent had an excellent outcome. Schurch and coworkers obtained improvement of pain and motor weakness in 5 of their 7 cases by stabilization of the spine and syringotomy with placement of a T-tube within the syrinx. In a more recent and comprehensive study of 73 patients with a developmental syrinx operated by Sgouros and Williams, one-half remained clinically stable for a 10-year period; 15 percent had serious complications of the surgery, however. Our experience with this procedure has not persuaded us of its lasting value; most of these patients, even those who reported some improvement originally, soon relapsed to their preoperative state, and the disease then progressed in the usual way. An enlarged cervical cord with progressive clinical worsening may nonetheless justify an attempt to shunt the cavity.

Surgery for the posttraumatic cases has given only slightly more favorable results. With incomplete myelopathy, syringostomy relieved the pain in all the 10 patients of Shannon and associates. Where they found the myelopathy to be complete, the cord was transected and the upper stump excised. Sgouros and Williams have also studied 57 such patients and recommend decompressive laminectomy and reconstruction of the subarachnoid space as the most effective of the several procedures that have been used in the management of traumatic cavities. An extensive review of surgical approaches to syringomyelia can be found in the article by Brodbelt and Stoodley. They tentatively recommend lysis of arachnoidal adhesions as preferable to shunting or filling of the cord but they acknowledge that the current state of treatment is not satisfactory.

In the cases of syringomyelia with tumor, in which the cyst fluid may be high in protein and viscid (unlike the low-protein fluid of the usual syrinx), the tumor should be excised if possible. This has been done successfully with hemangioblastomas of the posterior columns and occasionally with ependymomas.

The infrequent symptomatic purely hydromyelic cases may benefit from ventriculoperitoneal shunts of hydrocephalus, and a few excellent results are reported. This procedure has also been attempted in type I developmental cases, with unimpressive results unless there is an associated hydrocephalus. Draining the central canal by amputation of the tip of the sacral cord has been unsuccessful and can be harmful. Most cases do not require treatment.

**CONCLUDING REMARKS ON DISEASES OF THE SPINAL CORD**

It is always well to remind oneself that of the more than 30 diseases of the spinal cord, effective means of treatment are available for many of the common ones: spondylosis, extramedullary spinal cord tumors, syphilis (meningomyelitis and tabes), epidural abscess, he-
matoma and granuloma (tuberculous, fungal, sarcoidosis), perhaps syringomyelia, and subacute combined degeneration and other forms of nutritional myelopathy among others. Some of the inflammatory myelopathies may respond to immune modulating measures. The physician’s major responsibility is to determine whether the patient has one of these treatable diseases.

CHAPTER 44 DISEASES OF THE SPINAL CORD

CHAPTER 45

ELECTROPHYSIOLOGIC AND LABORATORY AIDS IN THE DIAGNOSIS OF NEUROMUSCULAR DISEASE

The clinical suspicion of neuromuscular disease, disclosed by any of the symptoms or syndromes in the succeeding chapters, finds ready confirmation in the laboratory. The intelligent selection of ancillary examinations requires some knowledge of the biochemistry and physiology of muscle fiber contraction, nerve action potentials, and neuromuscular conduction. These basic subjects, with the relevant anatomy, serve as an introduction to the descriptions of the laboratory methods and the subject matter of the chapters that follow.

ELECTROLYTES AND NEUROMUSCULAR ACTIVITY

It is not possible here to review all the biochemical and biophysical data that explain nerve impulse generation and conduction. Since the early studies of Hodgkin (1951) and of Hodgkin and Huxley (1952), tomes have been written on these subjects. Suffice it to say that the nerve and muscle fibers, like other bodily cells, maintain a fluid internal environment that is distinctly different from the external or interstitial medium. The main intracellular constituents are potassium (K), magnesium (Mg), and phosphorus (P), whereas those outside the cell are sodium (Na), calcium (Ca), and chloride (Cl). In both nerve and muscle the intracellular concentrations of these ions are held within a narrow range by electrical and chemical forces, which maintain the membranes in electrochemical equilibrium (“resting membrane potential”). These forces are the result of selective permeability of the membranes to various ions and the continuous expulsion of intracellular Na through special channels by a pump mechanism (“the sodium pump”). The function of the pump is dependent on the enzyme Na-K-ATPase, which is localized in the membranes.

This resting membrane potential is therefore dependent on the differential concentrations of K and Na. The interior of the cell is some 30 times richer in K than the extracellular fluid, and the concentration of Na is 10 to 12 times greater in the extracellular fluid. In the resting state, the chemical forces that promote diffusion of K ions out of the cell (down their concentration gradient) are counterbalanced by electrical forces (the internal negativity opposes further diffusion of K to the exterior of the cell). At the resting potential, the situation of Na ions is the opposite; they tend to diffuse into the cell, both because of their concentration gradient and because of the relative negativity inside the cell. Because the resting membrane is less permeable to Na than to K, the amount of K leaving the cell exceeds the amount of Na entering the cell, thus creating the difference in electrical charge across the membrane. This discrepancy, in association with the actions of the electrogenic Na:K pump and the presence of impermeant, negatively charged intracellular proteins, creates an electrical potential across the membrane such that, in the resting state, the intracellular compartment is 70 to 90 mV negative (the resting membrane potential).

Electrical discharge of neural and muscular tissue is predicated on a special property of excitable membranes—namely, that the permeability of the cell to Na is controlled by the electrical potential of the membrane. As the membrane is depolarized by any slight electrical or chemical change, there is an increased permeability to Na. The subsequent movement of K outward repolarizes the membrane and thereby reduces its permeability to Na. If a greater degree of depolarization occurs, a situation arises in which the outward movement of K is unable to stabilize the membrane potential. The membrane then becomes even more depolarized and progressively more permeable to Na, and an “explosive,” or regenerative Na current develops; sodium rushes down its chemical and electrical gradients into the cell. With the elevation in Na permeability, the Na ions would continue to depolarize the intracellular compartment to about +40 mV (the Nernst equilibrium potential for Na). Indeed, it is this depolarization of the intracellular compartment, lasting a few milliseconds, that constitutes the action potential. However, an equilibrium is not established, because there is a rapid (within 5 ms) fall in membrane Na permeability back to baseline levels. This fall in Na permeability occurs because the initial depolarization inactivates the Na conductance.

The transient depolarization at the same time activates an increase in membrane permeability to K. The combined effects of the resulting efflux of K and a diminishing influx of Na repolarize the membrane to a resting level. During a brief period immediately after repolarization, the nerve and muscle fibers are refractory, at first absolutely then relatively, to another depolarizing stimulus. The duration of the refractory period is determined largely by the duration of the inactivation of the Na channel.

Conduction, or propagation of the action potential along excitable nerve or muscle membranes, occurs as the current flows into the contiguous membrane, which in turn becomes depolarized. When the depolarization reaches the threshold for development of an action potential, a new zone of increased Na permeability is created. In this manner, the action potential then spreads in an all-or-none fashion, down the length of the nerve or muscle membrane (see Kuffler et al for further details). The action potentials in individual nerve fibers are too small and brief to be detected by conventional nerve conduction techniques, but a summated volley of all the fibers comprised by a nerve is large enough to be recorded, and it is this property that is utilized to study nerve function in the clinical electromyography (EMG) laboratory.

As the motor nerve impulses pass centrifugally from the axon into its terminal branches, transmission may still “break down,” especially if the repetition rate is excessive and impulses arrive too frequently at branch points. Impulses may then fail to reach the myoneural junction of these fibers; or there may be failure of con-
duction at the myoneural junction, which is what occurs in myasthenia gravis.

In large motor and sensory nerves, contiguous spread of action potentials along a fiber is slow and eventually decays over long distances. In these large fibers, conduction is aided by the structure and configuration of the myelin sheaths. The sodium channels, which generate the action potential, are concentrated at short exposed segments of the axon, the nodes of Ranvier, lying between longer segments of myelinated axon. The portions of axon that are covered by myelin remain electrically insulated. This creates “flux lines” that converge on the nodes and allows current to be regenerated at each of these gaps in the myelin. The speed of electrical conduction, which jumps in a “saltatory” fashion from node to node, is many times faster than conduction through an unmyelinated axon. The largest-diameter fibers, which by reason of their size have the fastest conduction times, also have the thickest myelin sheaths and longest internodal distances.

Conventional laboratory studies of nerve conduction generally measure the speed of these fastest-conducting fibers. This dependence of nerve conduction on the myelin sheath explains a number of electrophysiologic abnormalities that are a consequence of myelin destruction. One common finding, as one might predict, is a slowing of nerve conduction due to loss of the impulses contributed by the largest-diameter and fastest-conducting fibers. When myelin destruction is severe or a circulating factor impedes the channels that regenerate a sodium current, there is a total block of electrical conduction. An intermediate state of partial demyelination slows and desynchronizes the electrical volley, leading to temporal dispersion of the action potentials that reach the muscle. The cumulative effect of these changes is to reduce the number of nerve fibers that are capable of conducting an electrical volley, leading to a gradually reduced amplitude in the muscle action potential over longer segments of nerve. This reduction in amplitude of the compound motor action potential (CMAP) as the stimulating electrode is moved proximally is termed compound motor action potential (CMAP) as the stimulating electrode is moved proximally and has same staining reactions as sarcolemmal nuclei (M). Ramifications of axis cylinder (telodendria) lie in grooves or pouches in granular sarcoplasm, each lined by spiny “subneural apparatus” of Couteaux, which is continuous with membranous sarcolemna and also Schwann membrane. Nucleus (S) of sheath of Schwann commonly lies near point of branching of axon. Sheath of Henle has small nuclei (H) and fuses with endomysial sheath of muscle fiber. (Courtesy of Dr. D. Denny-Brown.)

Conventional laboratory studies of nerve conduction generally measure the speed of these fastest-conducting fibers. This dependence of nerve conduction on the myelin sheath explains a number of electrophysiologic abnormalities that are a consequence of myelin destruction. One common finding, as one might predict, is a slowing of nerve conduction due to loss of the impulses contributed by the largest-diameter and fastest-conducting fibers. When myelin destruction is severe or a circulating factor impedes the channels that regenerate a sodium current, there is a total block of electrical conduction. An intermediate state of partial demyelination slows and desynchronizes the electrical volley, leading to temporal dispersion of the action potentials that reach the muscle. The cumulative effect of these changes is to reduce the number of nerve fibers that are capable of conducting an electrical volley, leading to a gradually reduced amplitude in the muscle action potential over longer segments of nerve. This reduction in amplitude of the compound motor action potential (CMAP) as the stimulating electrode is moved proximally is termed compound motor action potential (CMAP) as the stimulating electrode is moved proximally. Blocking conduction of this nature is the most reliable marker of an acquired demyelinating neuropathy; of all the electromyographic changes, it corresponds most closely to the degree of muscle weakness (see further on).

In contrast to these effects of demyelination of peripheral nerve, the result of loss of axon fibers is a reduction in the summed electrical activity of the attached muscle and an atrophic denervation as described further on.

**THE NEUROMUSCULAR JUNCTION (MOTOR END PLATE)**

This is the interface between the finely branched nerve fiber and the muscle fiber, where the electrical activity of the motor nerve is translated into muscle action (Fig. 45-1). The nerve fiber contacts the muscle membrane in a trough-like junctional space of 50 mm—the synaptic cleft—between the axolemma and sarcolemma (see Fig. 53-1). Within the nerve terminal, a relatively fixed number of packets, or quanta, of acetylcholine (ACh), each packet containing about 10,000 molecules, are liberated through an exocytotic process by the arrival of axonal action potentials. Arrival of the electrical impulse opens calcium channels in the presynaptic membrane, which serve to bind packets of ACh to the membrane and govern their release. Molecules of ACh diffuse into the synaptic cleft and attach to receptor sites on the postsynaptic membrane. Each impulse triggers the release of approximately 200 quanta of ACh and produces a depolarization of sufficient size to initiate an action potential in the muscle through the same mechanism of a regenerative sodium current described earlier. Botulinum toxin and a high concentration of Mg ions interfere with the entry of calcium on the presynaptic side and raise the threshold for quantal release. There is also a nonquantal release of ACh through continuous leakage. This appears to play a role in the trophic influence of nerve on muscle.

The ACh molecule binds to the postsynaptic ACh receptor, a complex of five proteins that constitute the postsynaptic ion channel. Binding of ACh by this receptor causes a conformational change in the ACh receptor that leads to a local increase in the conductance of Na and K and other small ions. This produces a depolarization known as the end-plate potential. Small (miniature) end-plate potentials (MEPPs) are continuously formed and generated as the membranes repolarize, much as in the process of passive decay previously described. These potentials are too small to be recorded by routine EMG testing, although fortuitous needle placement adjacent to a synapse may detect them. The bound ACh is hydrolyzed by cholinesterase, a glycoprotein enzyme that exists in free form in the cleft. Its main function is to terminate the action potential and permit the sequential activation of muscle. The postsynaptic membrane, once depolarized, is refractory to another action potential until it is repolarized.

The calcium that entered the presynaptic nerve terminal is sequestered and then extruded and the choline from the hydrolyzed ACh enters the nerve terminal, where it is resynthesized to ACh near the release sites.

The analysis of a rapid series of electrically elicited muscle contractions is used specifically to analyze the function of the neuromuscular junction. In general, a decrement in the amplitude of
serial muscle action potentials is typical of postsynaptic failure of conduction, and an increment in the amplitude from a train of stimuli is a reflection of presynaptic failure. *Myasthenia gravis* is the principal disease affecting the neuromuscular junction. The fundamental defect is not a deficiency of ACh or its release, but rather its failure to attach to the postsynaptic receptor, which is blocked by an antibody at the receptor site. There are several other synaptic disorders—due to botulism, aminoglycoside antibiotics, and the antibodies of the Lambert-Eaton myasthenic syndrome—which impede presynaptic release of ACh. Certain pharmacologic agents interfere with neuromuscular transmission by combining with the cholinergic (nicotinic) receptor on the postsynaptic membrane, thereby competitively blocking the transmitter action of ACh. The curariform drugs, derived from curare and termed *nondepolarizing neuromuscular blockers*, are the main examples. Other drugs, notably succinylcholine and decamethonium, cause neuromuscular blockage by producing direct depolarization of the end plate and adjacent sarcoplasmic membrane (depolarizing neuromuscular blockers). Agents that inactivate cholinesterase have the opposite effect, i.e., they enhance the action of ACh. The ones in clinical use for the treatment of myasthenia gravis are the carbamates neostigmine, physostigmine, and pyridostigmine, the effects of which are reversible. The organophosphates are irreversible blockers of cholinesterase function, for which reason they are feared weapons of chemical warfare. Atropine is a potent cholinergic antagonist that is active only at muscarinic sites and therefore has no effect at the neuromuscular junction.

**BIOCHEMISTRY OF MUSCLE CONTRACTION**

The sarcolemma, the transverse tubules, and the sarcoplasmic reticulum each play a role in the control of the activity of muscle fibers. The structural components involved in excitation, contraction, and relaxation of muscle are illustrated in Fig. 45-2. Following nerve stimulation, an action potential is transmitted by the sarcolemma from the motor end-plate region to both ends of the muscle fiber. Depolarization spreads quickly to the interior of the fiber along the walls of the transverse tubules, probably by a conducted action potential. The transverse tubules and the terminal cisternae of the sarcoplasmic reticulum come into close proximity at points referred to as *triads*. Here, depolarization of the transverse tubules alters the conformation of a voltage-sensitive calcium channel in the transverse tubule membrane. This causes a large protein (the ryanodine receptor) in the membrane of the adjacent sarcoplasmic reticulum (SR) to open an internal calcium pore, allowing stored calcium to exit the SR and flood into the cytoplasm. The released calcium binds to the regulatory protein *troponin*, thereby removing the inhibition exerted by the troponin-tropomyosin system upon the contractile protein *actin*. This allows an interaction to take place between the actin molecules and the cross-bridges of the myosin molecules in the thick filaments and enables myosin adenosine triphosphatase (ATPase) to split adenosine triphosphate (ATP) at a rapid rate, thereby providing the energy for contraction. This chemical change allows the filaments to slide past each other, thereby shortening the muscle fiber. Relaxation occurs as a result of active (energy-dependent) Ca reuptake by the sarcoplasmic reticulum.

The pyrophosphate bonds of ATP, which supply the energy for muscle contraction, must be replenished constantly by a reaction that involves interchanges with the muscle phosphagen creatine diphosphate, where high-energy phosphate bonds are stored. These interactions, in both contraction and relaxation, require the action of creatine kinase (CK). Myoglobin, another important muscle protein, functions in the transfer of oxygen, and a series of oxidative enzymes are involved in this exchange. The intracellular Ca, as noted earlier, is released by the muscle action potential and must be reaccumulated within the cisternae of the sarcoplasmic reticulum before actin and myosin filaments can slide back past one another in relaxation. This reuptake of Ca requires the expenditure of considerable energy. When there is defective generation of ATP, for example, from an enzyme deficiency, the muscle
remains shortened, as in the contracture of phosphorylase deficiency (McArdle disease) or of phosphofructokinase deficiency. The same sort of shortening occurs under normal conditions in some of the “catch muscles” of certain mollusks and is the basis of rigor mortis in mammals.

Many glycolytic and other enzymes (transaminases, aldolase, CK) are utilized in the metabolic activity of muscle, particularly under relatively anaerobic conditions. Muscle fibers differ from one another in their relative content of oxidative and glycolytic enzymes; the latter determine the capacity of the muscle fiber to sustain anaerobic metabolism during periods of contraction with inadequate blood flow. Muscle cells rich in oxidative enzymes (type 1 fibers) contain more mitochondria and larger amounts of myoglobin (therefore appearing red), have slower rates of contraction and relaxation, fire more tonically, and are less fatigable than muscle fibers poor in oxidative enzymes. The latter (type 2 fibers) fire in bursts and are utilized in quick phasic rather than sustained re-actions. The amount of myosin ATPase activity, which governs the speed of contraction, is low in oxidative-rich fibers and high in glycolytic-rich fibers. The myosin ATPase stain at pH 9.4 has been used to identify these two types of fibers in microscopic sections. Type 1 fibers have a low content of myosin ATPase, and type 2 (phosphorylative-rich) fibers have a high content of this enzyme; hence type 1 fibers stain lightly and type 2 darkly (the reverse reaction occurs at pH 4.6). All the fibers within one motor unit are of the same type, a feature that is used to identify the reinnervation of muscle fibers by a single motor neuron after adjacent neurons have died and denervated their constituent muscle fibers (fiber type grouping).

The chemical energy required to maintain the various activities of the muscle cell is derived mainly from the metabolism of carbohydrate (blood glucose, muscle glycogen) and fatty acids (plasma free fatty acids, esterified fatty acids, and ketone bodies). There is a lesser contribution from branched-chain and other amino acids, but this may increase during prolonged exercise.

The most readily available source of energy is glycogen, which is synthesized and stored in muscle cells. It provides over 90 percent of the energy needs of muscle under conditions of high work intensity and during the early stages of submaximal exercise. Blood glucose and free fatty acids supplement intracellular glycogen as exercise proceeds. The free fatty acids are obtained from endogenous triglycerides (found mostly in type 1 fibers), from the triglycerides released by circulating lipoproteins, and from the lipolysis of adipose tissue. Most of the energy needs of resting muscle are provided by fatty acids.

The enzymatic reactions involved in the transport of these substrates into muscle cells and their intracellular synthesis and degradation during anaerobic and aerobic cell conditions have been thoroughly investigated and most of the enzymes identified. This subject is too complicated to present in a textbook of neurology, but enough is known about these matters to state confidently that there are a number of diseases that can impair the contractile functions of muscle in different ways without destroying the fiber. Specific enzymatic deficiencies under genetic control may affect carbohydrate utilization (myophosphorylase, debrancher enzyme, phosphofructokinase, phosphoglyceromutase, and myoadenylate deaminase), fatty acid utilization (carnitine and carnitine palmitoyl transferase deficiencies), pyruvate metabolism, and cytochrome oxidase activity (in the mitochondrial diseases). These enzymatic disturbances are discussed in later chapters.

**PHYSIOLOGY OF MUSCLE CONTRACTION**

The contraction of a muscle fiber is to be viewed as both a series of electrochemical events and a mechanical event. The mechanical change far outlasts the electrical one and extends through the period when the muscle fiber is refractory to another action potential. When a second muscle action potential arrives, after the refractory phase of the previous action potential but before the muscle has relaxed, the contraction will be prolonged. Thus, at frequencies of anterior horn cell firing of more than 100 per second, the twitches fuse into a sustained contraction or fused tetanus. In most sustained contractions, there is incomplete tetanus, attained by firing rates of 40 to 50 per second. In this fashion the mechanical phenomena are smoothed into a continuous process, even though the electrical potentials present as a series of depolarizations, separated by intervals during which the muscle membrane resumes its resting polarized state.

As pointed out in Chap. 3, the physiology of muscle activity should always be considered in terms of motor units, i.e., the group of muscle fibers within the domain of a single anterior horn cell. The strength of muscle contraction is a function of the number and rates of firing of many motor units. The smoothness of contraction depends on the integrated enlistment of motor units of increasing size. The electrical signal of this summated contraction, as recorded at the skin surface over a muscle, is the main feature of the surface EMG and the basis for quantifying the size of the motor potential in the motor nerve conduction examinations.

If the motor units are stimulated by a brief electrical stimulus applied to a motor nerve, the effect is a CMAP as just described (the summated amplitude produced by all the innervating nerve fibers). The CMAP can be visualized on the screen of an oscilloscope or a computer and its onset used to measure the speed of motor nerve conduction and the summed amplitudes produced by all the innervating nerve fibers. It can also be converted into an audible noise. Further study involves the insertion into the muscle of a coaxial needle, which samples several motor units in the vicinity of the electrode. When elicited by a sustained voluntary contraction, the flurry of electrical activity from many units at different distances from the electrodes is referred to as an interference pattern (see further on, under “Studies of Nerve Conduction” and “Needle Examination of Muscle”).

Biochemical changes may cause not only an impairment of neuromuscular activity (paresis, paralysis) but also excessive irritability, tetany, spasm, and cramp. In the latter instances, spontaneous discharges may occur from an instability of axon polarization; hence a single nerve impulse may initiate a train of action potentials in nerve and muscle, as in the tetany of hypocalcemia and in hemifacial spasm. The common cramps of calf and foot muscles (painful, sustained contractions with motor unit discharges at frequencies up to 200 per second) may be due to increased excitability (or unstable polarization) of the motor axons. Quinine, procainamide, diphenhydramine, and warmth reduce the irritability of nerve and muscle fiber membranes, as do a number of anticonvulsant drugs that act by blocking sodium channels and thereby limiting spontaneous membrane discharges.

To summarize, the muscle fiber, which is wholly dependent on the nerve for its stimulus to contract, may be physiologically activated or paralyzed in a number of ways. The motor nerve cell or its axon may be injured or inexcitable, in which case the muscle
cannot be stimulated. On the other hand, the nerve cell may be disinhibited in the anterior horn of the spinal cord, permitting the discharge of continuous action potentials, as in tetanus and the “stiff-man” syndrome (page 1279); the nerve fiber may fail to conduct impulses (demyelinating neuropathies) or the number of fibers may be inadequate to produce a fused and sustained contraction (axonal neuropathies); the neurilemma may not distribute the nerve impulse simultaneously to all parts of the motor unit; ACh may not be released at the presynaptic region of the neuromuscular junction (as occurs in botulism and in the Eaton-Lambert syndrome) or, once released, ACh may not be inactivated by cholinesterase (physostigmine, organophosphates); the receptor zone on the postsynaptic membrane may be destroyed or blocked by antibodies or pharmacologic agents (myasthenia gravis or curariform drugs); and, finally, the metabolic or contractile elements of the muscle may not react or, once contracted, may not relax. Similarly, the mechanisms involved in fasciculations, cramps, and muscle spasms may be traced to a number of different loci in the neuromuscular apparatus. There may be an unstable polarization of the nerve fibers, as in tetany and in dehydration with salt depletion, or unexplained hyperirritability of the motor unit, as in amyotrophic lateral sclerosis. The threshold of mechanical activation or electrical reactivation of the sarcolemmal membrane may be reduced, as in myotonia, or impairment of an energy mechanism within the fiber may slow the contractile process, as in hypothyroidism; or a deficiency of phospholipase, which dephosphorylates muscle of its carbohydrate energy source, may prevent relaxation, as in the contracture of McArdle disease. Lesions of the most peripheral branches of nerves, which allow nerve regeneration, may give rise to continuous activity of motor units. This is expressed clinically as a rippling of muscle, or myokymia (see pages 1104 and 1278).

In recent years, new technologies have made it possible to isolate each of the proteins and channels involved in neuromuscular transmission and the excitation-contraction-relaxation of muscle fibers. The amino acid composition of most of these proteins has also been determined. This information is being increasingly applied to the analysis of gene products in the normal state and under conditions of disease. Pertinent comments and references to this subject are found in the chapters that follow.

**EFFECTS ON MUSCLE OF ABNORMALITIES OF SERUM ELECTROLYTES**

Diffuse muscle weakness or muscle twitching, spasms, and cramps should always raise the question of uremia or an abnormality in serum electrolytes. These disorders reflect the concentrations of serum electrolytes. These disorders reflect the concentrations of calcium (as in rickets or hypoparathyroidism) or relative reduction in the proportion of ionized calcium (as in hyperventilation) causes increased muscle irritability and spontaneous discharge of sensory and motor nerve fibers (i.e., tetany) and sometimes convulsions from similar effects upon cerebral neurons; frequent repetitive and finally prolonged spontaneous discharges grouped in couplets or triplets appear in the EMG, and convulsive effects are reflected in the electroencephalogram. Hypercalcemia above 12 mg/dL (as occurs in vitamin D intoxication, hyperparathyroidism, carcinomatosis, sarcoid, and multiple myeloma) causes weakness and lethargy, perhaps on a central basis. Extreme hypophosphatemia, observed most often with intravenous hyperalimentation or bone tumor, can cause acute areflexic paralysis with nerve conduction abnormalities. Reduction in the plasma concentration of magnesium also results in tremor, muscle weakness, tetanic muscle spasms, and convulsions; a considerable increase in magnesium levels leads to muscle weakness and depression of central nervous function. The weakness of muscle in hypermagnesemia may also be due, in part at least, to reduced release of ACh at the motor end plate. The electrocardiogram (ECG) also becomes abnormal with many of these systemic electrolyte derangements as a result of alterations of the intracellular levels of electrolytes in the myocardium; ECG patterns are most sensitive to extreme changes in serum potassium levels.

**CHANGES IN SERUM LEVELS OF ENZYMES ORIGINATING IN MUSCLE CELLS**

In all diseases causing extensive damage to striated muscle fibers, intracellular enzymes leak out of the fiber and enter the blood. Those measured routinely are the transaminases, lactic acid dehydrogenase, aldolase, and especially, CK. Of these, the concentration of CK in serum has proved to be the most sensitive measure of muscle damage. Since high concentrations of this enzyme are found in heart muscle and brain, raised serum values may be due to myocardial or cerebral infarction as well as to the necrotizing diseases of striated muscle (polymyositis, muscle trauma, muscle infarction, paroxysmal myoglobinuria, and the more rapidly advancing muscular dystrophies). For serum CK levels to be interpretable, one has to be certain that the enzyme released into the serum is not derived from heart or brain. This can be determined by the quantitation of serum isoenzymes of CK, referred to as MB, MM, and BB (M, muscle; B, brain); their measurement provides a sensitive means for the detection of damage to myocardium (MB), skeletal muscle (MM), and nervous tissue (BB), respectively.

The MM form of CK is found in highest concentration in striated muscle, but these muscles also contain 5 to 6 percent MB. Myocardial tissue contains 17 to 59 percent MB; hence, the diagnosis of myocardial infarction requires that the CK-MB fraction be greater than 6 percent (or that troponin, which is overrepresented in heart muscle, be elevated in the serum). Embryonic and regenerating muscle contains more CK-MB than mature normal muscle. In patients with destructive lesions of striated muscle, serum values of CK often exceed 1000 U and may reach 40,000 U or more (the upper limit of normal varies from 65 to 200 U, depending on the method of measurement). Serum of the healthy adult contains only the MM isoenzyme, but in healthy children, as much as 25 percent of serum CK may be derived from the MB fraction. Even more interesting is the rise in serum enzyme concentration in some children with progressive muscular dystrophy before there is enough destruction of fibers for the disease to be clinically manifest, at least as judged by the relatively crude tests of muscle strength. Moreover, the unaffected female carrier of Duchenne dystrophy may be identified by an elevated serum level of CK. Alterations of serum enzyme levels are nonspecific for dystrophy since they occur...
in all types of disease that damage the muscle fiber. Moreover, in the more slowly evolving types of dystrophy, such as that of Landouzy-Déjerine, the serum levels of CK may be normal. It would be expected that the values would always be normal in denervation paralysis with muscular atrophy, but elevations are sometimes observed in patients with progressive spinal muscular atrophy and amyotrophic lateral sclerosis particularly if there is relatively rapid progression of muscle denervation. Even vigorous exercise or surgical operations involving muscle elevate CK, sometimes exceeding 6 percent from the MB fraction.

**HyperCKemia** In some individuals, CK may be persistently elevated without evidence of muscle or other diseases ("idiopathic hyperCKemia"); there is a particularly high incidence of this finding, albeit of mild degree, in African-American men. An unexplained alteration of the sarcolemma with elevated serum CK occurs in hypothyroidism and in alcoholism. Toxic myopathies, for example the type caused by the cholesterol-lowering drugs, are a common cause of elevation in CK. Among the most commonly defined causes of persistently elevated CK are underlying inherited muscle defects, usually one of the varieties of dystrophinopathy. Detailed examination will usually reveal slight proximal weakness and perhaps minimal calf enlargement characteristic of the mildest forms of Becker dystrophy. Closely related is the finding of CK elevations that occur in females who are asymptomatic carriers of Duchenne or Becker dystrophy. In these latter instances, muscle biopsy shows a mosaic pattern of dystrophin immunostaining; i.e., some fibers contain dystrophin and others do not. Several other inherited muscle diseases present as hyperCKemia including carnitine palmitoyl transferase deficiency, myoadenylate deaminase deficiency, some of the mitochondrial myopathies, sarcoid myopathy, McArdle disease, central core disease, multicore disease, and some forms of inclusion body myopathy. Miyoshi myopathy, the distal myopathy that arises in young adults with dystrophin deficiency, can also present in the late teens or early twenties as an asymptomatic but very substantial CK elevation; in this instance, as in some of the preceding disorders, the initial, seemingly benign CK elevation, is followed by progressive distal weakness. HyperCKemia has also been correlated with subclinical mutations in the genes for caveolin-3 and titin.

If other sources of an elevated CK level that persists for months or longer have been excluded, particularly those due to exercise and to drug induced muscle damage, it is appropriate to follow the patient over time in order to detect mild weakness, or to perform a biopsy in order to resolve the issue of a mild or early muscular dystrophy.

An isolated elevation of aldolase, the serum enzyme other than CK that is derived predominantly from skeletal muscle, generally has less clinical significance. Measurement in the serum of various transaminases or lactate dehydrogenase is not particularly useful for the diagnosis of muscle disease because of their ubiquitous distribution in many mammalian tissues. Nevertheless, the neurologist should be aware that unexplained elevations in all of the muscle-derived enzymes (CK, LDH, S GOT, aldolase, etc.) can be caused by invident muscle trauma and by other processes that damage the muscle membrane.

**MYOGLOBINURIA**

The red pigment myoglobin, responsible for much of the color of muscle, is an iron-protein compound present in the sarcoplasm of striated skeletal and cardiac fibers. Of the total body hematin compounds, about 25 percent is in muscle, the remainder in red blood corpuscles and other cells. Destruction of striated muscle, regardless of the process—whether trauma, ischemia, or metabolic disease—liberates myoglobin, and because of its relatively small size, the molecule filters through the glomeruli and appears in the urine, imparting to it a burgundy red color. Because of the low renal threshold for myoglobin, excretion of this pigment is so rapid that the serum remains uncolored. In contrast, because of the high renal threshold for hemoglobin, destruction of red blood corpuscles-color both the serum and the urine. Myoglobinuria should thus be suspected when the urine is deep red and the serum is normal in color. It is estimated that 200 g of muscle must be destroyed to color the urine visibly (Rowland). As in hemoglobinuria, the guaiac and benzidine tests of urine are positive if myoglobin is present. The colored urine does not fluoresce, as it does in porphyria. On spectroscopic analysis, myoglobin shows an absorption band at 581 nm, but the most sensitive method for measuring myoglobin in the urine and serum is by radioimmunoassay (Rosano and Kenny). Hyperkalemia, hyperphosphatemia, and hypercalcemia may complicate massive rhabdomyolysis.

Some years ago, the measurement of creatine and creatinine in blood and urine was a standard method of estimating damage to striated muscle. This technique is now seldom used for clinical or research purposes, having been replaced largely by the measurement of CK and its isoenzymes.

**ENDOCRINE MYOPATHIES**

In a number of disorders of the endocrine glands, muscle weakness may be a prominent feature, and occasionally it may be the chief complaint. Although these diseases are discussed in detail in Chap. 51, it should be noted that such metabolic muscle weakness, acute or chronic, may occur in the absence of changes in serum electrolytes or enzymes. Specific hormone assays are then necessary for diagnosis. This is particularly true of patients with thyrotoxicosis or Cushing disease and those receiving prolonged corticosteroid therapy. In thyrotoxicosis, muscle paresis may appear without the classic signs of Graves disease.

**ELECTRODIAGNOSIS OF NEUROMUSCULAR DISEASE (ELECTROMYOGRAPHY; EMG)**

It was long ago discovered that muscle would contract when a pulse of electric current was applied to the skin, near the point of entrance of the muscular nerve (motor point). The electrical pulse required is brief, less than a millisecond, and is most effectively induced by a rapidly alternating (faradic) current. After denervation, an electrical pulse of several milliseconds, induced by a constant electrical (galvanic) stimulus, is required to produce the same response. This change, in which the galvanic stimulus remains effective after the faradic one has failed, was the basis of Erb’s reaction of degeneration, and varying degrees of this change were later plotted in the form of strength-duration curves. For decades, this was the standard electrical method for evaluating denervation of muscle. Though still valid, it was replaced long ago by nerve conduction studies and by the needle electrode examination. The latter test, based on the sherringtonian concept of the “motor unit” (page 39), is accomplished by recording the firing characteristics of evoked motor unit potentials (CMAPs) and by the insertion into muscle of needle electrodes to measure spontaneous and voluntar-
ily evoked muscle fiber activity. The terms electromyography and electromyogram (EMG) were used originally to describe the needle electrode examination but are now a common shorthand designation for the entire electrodiagnostic evaluation, including the nerve conduction studies, described below.

Studies of Nerve Conduction

The main laboratory technique for the study of peripheral nerve function involves the transcutaneous stimulation of motor or sensory nerves and recording of the elicited action potentials in the muscle (CMAP) and the sensory nerve action potential (SNAP). The results of these motor and sensory nerve conduction studies, expressed as amplitudes, conduction velocities, and distal latencies, yield certain quantitative information and additional qualitative observations regarding the waveform and dispersion of electrical impulses.

Hodes and coworkers in 1948 were the first to describe nerve conduction studies in patients and the techniques used currently are not much changed. An accessible nerve is stimulated through the skin by surface electrodes, using a stimulus that is large enough to recruit all the available nerve fibers. The resulting action potential is recorded by electrodes on the skin (1) over the muscle distally in the case of motor fibers stimulated in a mixed or motor nerve (CMAP), (2) over the nerve proximally, using orthodromic techniques for sensory fibers stimulated in the digital nerves, (3) over the nerve more distally, using antidromic techniques for sensory nerve conduction studies (this has technical advantages over orthodromic techniques), and (4) over the nerve more proximally for mixed nerve conduction studies (Fig. 45-3). These techniques are the ones used most often in clinical work. An alternative but much more demanding technique uses “near nerve” needle electrodes to record action potentials as they course through the nerve. The main characteristics of the conventional nerve conduction studies are described below.

Distal (Terminal) Latencies, Conduction Times, and Conduction Velocities

The conduction times from the most distal stimulating electrode to the recording site, in milliseconds, as determined by the latency from the stimulus artifact to the onset and to the peak of the CMAP, are termed the distal (or terminal) and peak motor latencies, respectively (see Fig. 45-3). The former is the one used more often as a reflection of conduction time in routine work. A stimulus may then be applied to the nerve at a second site more proximally (or if recording electrodes can be placed more proximally in the case of sensory fibers), and a conduction time can be measured over a longer segment of nerve. When the distance (in millimeters) between the two sites of stimulation is divided by the difference in conduction times (in milliseconds), one obtains a conduction velocity (in meters per second), which describes the maximal velocity of propagation of the action potentials in the largest diameter and fastest nerve fibers. These velocities in normal subjects vary from a minimum of 40 or 45 m/s to a maximum of 65 to 75 m/s, depending upon which nerve is studied (e.g., slower in the legs than in the arms; Table 45-1). Values are lower in infants, reaching the adult range by the age of 2 to 4 years and decline again slightly with advancing age. They are routinely diminished also with exposure to cold—a potentially important artifact if these recordings are taken when the patient’s skin is cool; measurement of skin temperature therefore is routinely made prior to performing the conduction tests.

Normal values have been established for distal latencies from the various sites of stimulation on various mixed nerves to the appropriate muscles. When one stimulates the median nerve at the wrist, for example (see electrode 1 and segment A in Fig. 45-3), the latency for motor conduction through the carpal tunnel to the median-innervated thenar muscles is always less than 4.5 ms in healthy adults. Similar normal values have been compiled for orthodromic and antidromic sensory conduction velocities and distal latencies (see Table 45-1) in all the main peripheral nerves.

Disease processes that preferentially injure the fastest-conducting, large-diameter fibers in peripheral nerves reduce the maximal conduction velocity because the remaining thinner fibers conduct more slowly. In most neuropathies, all of the axons are affected either by a fairly uniform “dying-back” phenomenon or by wallerian degeneration as described in Chap. 46, and nerve conduction velocities are then less informative. This is true for typical alcoholic-nutritional, carcinomatous, uremic, diabetic, and other metabolic neuropathies, in which conduction velocities range from low normal to mildly slowed. In these so-called “axonal neuropathies,” the motor and sensory nerve amplitudes are diminished (see below).

By contrast, demyelinating neuropathies of the acute (Guilain-Barré, diphtheria) and chronic types such as chronic inflammatory, metachromatic leukodystrophy, Krabbé disease, and the common type of Charcot-Marie-Tooth disease show marked slowing of conduction and, in the case of the acquired demyelinating diseases, there is also dispersion of the action potential and conduction block (see later).
Amplitude of the Compound Muscle Action Potential  In addition to the study of distal latency and conduction velocity, the amplitude of the evoked muscle action potential (CMAP) yields valuable information about peripheral nerve function. These amplitudes are a semiquantitative measure of the number of nerve fibers that respond to a maximal stimulus. Demyelinating lesions or axonal loss affecting the large, fast-conducting fibers may be detected by the finding of differential slowing among various caliber fibers that causes a dispersal of the CMAP response. Reduction in motor and sensory amplitudes is a more specific and sensitive indicator of axonal loss than is slowing of conduction velocity or prolongation of distal latencies. Conversely, prolonged distal latencies and slowed motor conduction velocities—as well as conduction blocks (described later) and dispersed responses—are the hallmarks of demyelinating lesions. The range of normal amplitudes for the CMAPs that are elicited by stimulation of the main muscle. However, when one attempts to measure sensory potentials, where activity must be recorded from nerve fibers themselves, the “amplification” provided by many motor units is not available and electronic amplification is required. Sensory potentials are sometimes very small or absent even when powerful computer-averaging techniques are used, and sensory conduction measurements may then be difficult to determine. Table 45-1 gives the range of normal values for sensory nerve action potential amplitudes and velocities.

Conduction Block  By stimulating a motor nerve at multiple sites along its course, it is possible to demonstrate segments in which conduction is partially “blocked” or is differentially slowed. From such data one infers the presence of a multifocal demyelinating process in motor nerves. This contrasts with the findings in certain of the inherited demyelinating neuropathies, in which all parts of the nerve fiber are altered to more or less the same degree, i.e., there is uniform slowing of conduction and no conduction block.

As a technical matter, conduction block is demonstrated by a reduction in the amplitude of the CMAP elicited from the proximal site along the motor nerve, compared to stimulation at a distal site. Generally, a 40 percent reduction in amplitude over a short distance of nerve, or 50 percent over a longer distance, qualifies as a block, one exception being along the tibial nerve, in which it is difficult to stimulate all the motor nerve fibers and in which some drop in amplitude is normally expected. It is also important to be sure that any reduction in amplitude along the course of the nerve is not due solely to dispersion of the waveform. One must also keep in mind that conduction block may be attributable simply to nerve compression at common sites (fibular head, across the elbow, flexor retinaculum at the wrist, etc.) rather than to an intrinsic disease of the peripheral nerves. The presence of a conduction block can also

Sensory Nerve Action Potentials  When motor fibers in a mixed nerve are stimulated, an amplified CMAP of many hundreds of microvolts can easily be recorded from electrodes on the skin over the muscle. However, when one attempts to measure sensory potentials, where activity must be recorded from nerve fibers themselves, the “amplification” provided by many motor units is not available and electronic amplification is required. Sensory potentials are sometimes very small or absent even when powerful computer-averaging techniques are used, and sensory conduction measurements may then be difficult to determine. Table 45-1 gives the range of normal values for sensory nerve action potential amplitudes and velocities.
be inferred from the finding of poor recruitment of muscle action potentials in the absence of active denervation (see further on).

As mentioned, the finding of conduction block is a central feature of a number of acquired immune demyelinating neuropathies, including Guillain-Barré syndrome, chronic inflammatory demyelinating neuropathy, and multifocal conduction block associated with the GM1 antibody, all of which are discussed in Chap. 46.

Focal compression of nerve, as occurs in the entrapment syndromes mentioned earlier, may produce localized slowing or blocks in conduction, perhaps because of segmental demyelination at the site of compression. The demonstration of such localized changes of conduction affords ready confirmation of nerve entrapment; for example, if the distal latency of the median nerve (see A, Fig. 45-3) exceeds 4.5 ms while that of the ulnar nerve remains normal, compression of the median nerve in the carpal tunnel is likely. Similar focal slowing or partial block of conduction may be recorded from the ulnar nerve at the elbow and from the peroneal nerve at the fibular head.

Special Electrodiagnostic Studies of Nerve Roots and Spinal Segments (Late Responses, Blink Responses, Segmental Evoked Responses)

H Reflex Information about the conduction of impulses through the proximal segments of a nerve is provided by the study of the H reflex and the F wave. In 1918, Hoffmann, after whom the H reflex was named, showed that submaximal stimulation of mixed motor-sensory nerves, insufficient to produce a direct motor response, induces a muscle contraction (H wave) after a latency that is far longer than that of the direct motor response. This reflex is based on the activation of afferent fibers from muscle spindles (the same axons that conduct the afferent volley of the tendon reflex), and the long delay reflects the time required for the impulses to reach the spinal cord via the sensory fibers, synapse with anterior horn cells, and to be transmitted along motor fibers to the muscle (see Fig. 3-1). Thus the H reflex is therefore the electrical representation of the tendon reflex circuit and is especially useful because the impulse traverses both the posterior and anterior spinal roots. The H reflex is particularly helpful in the diagnosis of S1 radiculopathy and of other polyradiculopathies. Its status generally parallels that of the Achilles reflex. However, it may be difficult to elicit an H reflex from nerves other than the tibial. Stimuli of increasing frequency but low intensity cause a progressive depression and finally obliteration of H waves. The latter phenomenon has been used to study spasticity, rigidity, and cerebellar ataxia, in which there are differences in the frequency-depression curves of H waves.

F Wave The F response, so named because it was initially elicited in the feet, was first described by Magladery and McDougal in 1950. It is evoked by a supramaximal stimulus of a mixed motor-sensory nerve. After a latency longer than that for the direct motor response (latencies of 28 to 32 ms in arms, 40 to 50 ms in legs), a second small muscle action potential is recorded (F wave). The F wave is the result of the impulses that travel antidromically in motor fibers to the anterior horn cells, a small number of which are activated and produce an orthodromic response that is recorded in a distal muscle. The response is a more reliable test than the H wave of proximal nerve and root conduction in that the F wave traverses only the ventral root and can be elicited from any number of muscles. The combination of a normal F response and an absent H reflex is found in diseases of sensory nerves and roots. Both of these “late responses” find their main use as corroborative tests that must be interpreted in the context of the entire nerve conduction examination (see Wilbourn in References). The normal late response latencies are given in Table 45-1.

Blink Responses This special nerve conduction test is useful in the diagnosis of certain demyelinating neuropathies and in any process that affects the trigeminal or facial nerve. The supraorbital (or infraorbital) nerve is stimulated transcutaneously and the reflex closure of both orbicularis oculi muscles is recorded with surface electrodes. Two CMAP bursts are observed: the first (R1) appears ipsilaterally 10 ms after the stimulus and the second (R2) ipsilaterally at 30 ms and contralaterally up to 5 ms later. The amplitudes of the responses vary considerably and are not in themselves clinically important. The first response is not visible as a muscular contraction but may serve some preparatory function by shortening the blink reflex delay. R1 is mediated by an oligosynaptic pontine circuit consisting of one to three neurons located in the vicinity of the main sensory nucleus; R2 utilizes a broader reflex pathway in the pons. It has been established that R1 and R2 are generated by the same facial motor neurons.

The elicitation of blink reflexes establishes the integrity of the afferent trigeminal nerve, the efferent facial nerve, and the interneurons in the pons (R1) and caudal medulla (related to the bilateral R2 response). The test may be also be helpful in identifying a demyelinating neuropathy when the facial and oropharyngeal muscles are affected and those of the limbs are relatively spared, leaving conventional nerve studies normal. In such cases, the blink responses are delayed ipsilaterally and contralaterally as a result of conduction block in the proximal facial nerve. Direct facial nerve stimulation often fails to demonstrate this block because only the distal segment of the nerve is amenable to study. Although this test is rarely necessary for diagnosis, most patients with hereditary neuropathy have blink response abnormalities. In Bell’s palsy there is a delay or absence of R1 and R2 responses only on the affected side. Large acoustic neuromas may interfere with the afferent trigeminal portion of the pathway and give rise to abnormal responses on the affected side. Diseases of the brainstem have yielded inconsistent responses. It is noteworthy that the test is normal in patients with trigeminal neuralgia.

Segmental Motor, Cranial, and Somatosensory Evoked Potentials (See also Chap. 2) These techniques find use in diseases that affect spinal roots. By applying a magnetic stimulus, which induces an electrical impulse, or by a directly delivered electrical stimulus over the lower cervical or lumbar spine, it is possible to activate the motor (anterior) roots and to measure the time required to elicit a muscle contraction (Cros and Chiappa). These root stimulation tests can be quite uncomfortable for the patient because of the contraction of muscles surrounding the stimulation site.

Transcranial magnetic stimulation of the cerebral cortex permits measurement of the latency of muscle contraction after excitation of motor neurons in the cortex. Thus, the integrity of the entire corticospinal system, from the cortical motor neurons through spinal tracts, anterior horn cells, and the peripheral motor nerve can be determined. By combining this technique with the previously described root stimulation, it becomes possible to measure central and peripheral motor conduction times. These forms
of testing have their main use in the study of amyotrophic lateral sclerosis (ALS) and related disorders.

As described in Chap. 2, by applying repetitive electrical stimuli to a peripheral nerve, the sensory evoked responses can be recorded from sites along the nerve and plexus as well as in central pathways (the thalamus and somatosensory cortex). These evoked potential tests find their main use in the diagnosis of multiple sclerosis and in disorders of the sensory nerve roots as discussed in Chaps. 2 and 36. Other special nerve conduction techniques are available in many laboratories. For details of their performance and interpretation the reader is referred to specialized texts on the subject. Discussion of magnetic stimulation, collision techniques, quantitative EMG, etc., can be found in several monographs, such as the ones by Kimura, by Aminoff, and by Brown and Bolton.

**Repetitive Motor Nerve Stimulation (Jolly Test)**

This test of the function of the neuromuscular junction is based on Jolly’s observation in 1895 that in myasthenia gravis the strength of muscular contractions progressively declines in response to a train of stimuli. By adjusting the amplitude of a stimulus over a nerve to supramaximal range, a maximal CMAP may be obtained for each stimulus. With repeated stimuli, each response will have the same waveform and amplitude until fatigue supervenes. In a healthy individual, the response follows each stimulus even with rates of stimulation up to 25 per second for periods of 60 s or more before a decrement of the CMAP appears. In certain disorders, notably myasthenia gravis, a train of 4 to 10 stimuli at rates of 2 to 5 per second (optimally 2 to 3 per second), the amplitude of the motor potentials decreases and then, after four or five further stimuli, may increase slightly (Fig. 45-4A). A progressive reduction in amplitude is most likely to be found in proximal muscles, but these are not easily stimulated for which reason the locations most commonly used for clinical testing are the accessory nerve in the posterior triangle of the neck (trapezius), the ulnar nerve (hypothenar muscle), the median nerve at the wrist (thenar muscle), and the facial nerve and orbicularis oculi muscle. A decrement of 10 percent or more denotes a failure of a proportion of the neuromuscular junctions that are being stimulated. The sensitivity of the procedure is improved by first exercising the tested muscle for 30 to 60 s. The induced failure of neuromuscular transmission in myasthenia gravis is similar to the one produced by curare and other nondepolarizing neuromuscular blocking agents, and both cases can be partially corrected with anticholinesterase drugs such as neostigmine and edrophonium. Similar but lesser decremental responses may occur in poliomyelitis, ALS, and certain other diseases of the motor unit or motor nerve, particularly those resulting in the growth of reinnervating nerve twigs.

The myasthenic syndrome of Lambert-Eaton, often associated with oat-cell carcinoma of the lung, is characterized by a presynaptic blockage of acetylcholine release and produces the opposite defect of neuromuscular transmission to the one recorded in myasthenia gravis. During tetanic stimulation (20- to 50-per-second repetitive stimulation of nerve), the muscle action potentials, which are small or practically absent with the first stimulus, increase in voltage with each successive response until a more nearly normal amplitude is attained (see Fig. 45-4B). Exercising the muscle for 10 s before stimulation will cause a similar posttetanic facilitation (200-fold increases are not uncommon). A less important decremental response to slow stimulation may occur, but it is difficult to discern because of the greatly diminished amplitude of the initial responses. Neostigmine has little effect on this phenomenon, but it may be reversed by guanidine and 3,4-diaminopyrididine, which stimulate the presynaptic release of ACh. The effects of botulinum toxin and of aminoglycoside antibiotics are similar, i.e., being active at the presynaptic membrane, they produce an incremental response at high rates of stimulation.

The single-fiber EMG, discussed in a later section, is an even more sensitive method of detecting failure of the neuromuscular junction.

**Needle Examination of Muscle (Electromyography)**

This technique requires the use of monopolar or concentric bipolar needle electrodes, which are inserted into the body of the muscle to record the electrical activity generated by contraction. With concentric needle electrodes, the tip of the wire that runs in the hollow of the needle is in proximity to many muscle fibers belonging to several different overlapping motor units; this is the active recording electrode. The shaft of the needle, in contact over most of its length with intercellular fluid and many other muscle fibers, serves as the reference electrode. With monopolar electrodes, the un insulated needle tip is the active electrode, while the reference electrode may be another monopolar needle electrode placed in subcutaneous tissue or a surface electrode on the skin overlying the muscle. Patients almost invariably find this portion of the test uncomfortable and should be prepared by a description of the procedure. Rapid and brief needle insertion by the skilled examiner makes the test more tolerable.

As the electrical impulse travels along the surface of the muscle toward the recording electrode, a positive potential is recorded on the oscilloscope, i.e., the recorded signal is deflected downward by convention (at A in Fig. 45-5). When the depolarized zone moves under the recording electrode, it becomes relatively negative and the beam is deflected upward (at B). As the depolarized zone continues to move along the sarcolemma, away from the recording electrode, the current begins to flow outward through the membrane toward the distant depolarized region, and the recording electrode

![Image](image-url)
of four or more phases (polyphasic potentials); an excess of polyphasic potentials beyond this is pathologic.

Normal muscle in the resting state should be electrically silent; the small tension spoken of as muscle tone has no EMG equivalent. There are, however, two closely related types of normal spontaneous activity and another that is induced by the insertion of the needle itself. One is a low-amplitude, 10- to 20-mV monophasic (negative) potential of very brief (0.5 to 1 ms) duration. These represent single or synchronized MEPPs due to the small number of ACh quanta that are being released all the time. They are normally sparse but are more evident when the recording needle electrode is placed near a motor end plate ("end-plate noise"). Fortuitous placement of the needle electrode very close to or in contact with the end plate gives rise to a second type of normal spontaneous activity. That is characterized by irregularly discharging high-frequency (50- to 100-Hz) biphasic spike discharges, 100 to 300 mV in amplitude (i.e., large enough to cause an isolated muscle action potential). These potentials have been termed end-plate spikes and represent discharges of single muscle fibers excited by spontaneous activity in nerve terminals. They must be distinguished from fibrillation potentials (see later). Finally, insertion of the needle electrode into the muscle injures and mechanically stimulates many fibers, causing a burst of potentials of short duration (300 ms). This is referred to as normal insertional activity.

When muscle is voluntarily contracted, the action potentials of motor units begin to appear. One can observe a pattern of force build up by watching the progressive recruitment of MUPs; the initial ones, representing smaller motor units, firing at rates of 5 to 10 per second. With increased force of contraction, there is recruitment of larger, previously inactive motor units as well as an increased rate of firing (40 to 50 per second; Fig. 45-6A). Since individual MUPs can no longer be distinguished during maximal voluntary contraction, this activity is referred to as a complete interference pattern (Fig. 45-6A, right). This is seen not only as a summated signal pattern but is also heard as a mixed high-frequency clicking when the electrical activity is made audible. As muscles relax, more and more units drop out. If a muscle is weakened by denervation or if electrical conduction is blocked, there will obviously be fewer MUPs, but the firing rate is still rapid (reduced recruitment, see Fig. 45-6B). In contrast, with poor voluntary effort and with upper motor neuron lesions, the MUPs fire in decreased numbers, at slower rates, and often in an irregular pattern (termed poor activation).

In the usual EMG examination, a plan for the study is made based on detailed knowledge of muscular innervation and focusing on the regions affected by weakness. In some patients, as in those with motor neuron diseases or polymyositis, a wider sampling of muscles is required to detect changes in asymptomatic regions.

The Abnormal Electromyogram Clinically important deviations from the normal EMG include (1) increased or decreased activity upon insertion of the needle; (2) the occurrence of abnormal “spontaneous" activity during the relaxed state (fibrillation potentials, positive sharp waves, fasciculation potentials, cramp potentials, myotonic discharges, myokymic potentials); (3) abnormalities in the amplitude, duration, and shape

Figure 45-5. The shaded area represents the zone of the action potential, which is negative to all other points on the fiber surface. It is shown at three points in its course (from left to right) along the fiber. At each point, the correspondingly lettered portion of the triphasic muscle action potential displayed on the display screen reflects the potential difference between the active (vertical arrow) and reference (Ref.) electrodes. Polarity in this and subsequent figures is negative upward as depicted. The time calibration is on the screen.

Figure 45-6. Patterns of motor unit recruitment. A. Normal. With each increment of voluntary effort, more and larger units are brought into play until, with full effort at the extreme right, a complete “interference pattern" is seen in which single units are no longer recognizable. B. After denervation, only a single motor unit is recorded despite maximal effort. It is seen to fire repetitively. C. With myopathic diseases, a normal number of units is recruited on minimal effort, though the amplitude of the pattern is reduced. Calibrations: 50 ms (horizontal) and 1 mV in A and B; 200 mV in C (vertical).
of single MUPs; (4) a decrease in the number of MUPs and changes in their firing pattern; (5) variation in amplitude and number of phases of MUPs during voluntary contraction of muscle; and (6) the demonstration of special phenomena, such as electrical silence during obvious shortening of the muscle (physiologic contracture).

**Insertional Activity** At the moment the needle is inserted into muscle, there is a brief burst of action potentials that ceases once the needle is stable, provided that it is not in a position to irritate a nerve terminal. Increased insertional activity is seen in most instances of denervation as well as in many forms of primary muscle disease and in disorders that dispose to muscle cramps. In cases of advanced denervation or myopathy, in which muscle fibers have been largely replaced by connective tissue and fat, insertional activity may be decreased and there is a palpable increase in mechanical resistance to the insertion of the needle.

**Abnormal “Spontaneous” Activity** With the muscle at rest, spontaneous activity of single muscle fibers and of motor units, known respectively as fibrillation potentials and fasciculation potentials, is abnormal. The two phenomena are often confused. Fibrillation is the spontaneous contraction of a single muscle fiber. It occurs when the muscle fiber has lost its nerve supply and is ordinarily not visible through the skin (but may be visible in the tongue). Fasciculation represents the spontaneous firing of an entire motor unit, causing contraction of a group of muscle fibers, and may be visible through the skin. The irregular firing of a number of motor units, seen as a rippling of the skin, is called myokymia.

**Fibrillation Potentials** When a motor neuron is destroyed by disease or its axon is interrupted, the distal part of the axon degenerates, a process that takes several days or more. The muscle fibers formerly innervated by the branches of the dead axon—that is, the motor unit—are disconnected from the nervous system. For reasons that are still obscure, the chemosensitive region of the sarcotendinous junction of the end-plate zone is then depolarized, setting up a wave of depolarization that spreads along the muscle fiber. For several millimeters, the depolarization is propagated in a direction opposite to that of its generation. Other physiological and pharmacological evidence points to the anterior horn cell or the motor root, but more probably in the case of benign fasciculations) as the source of the fibrillation potentials (Fig. 45-7A) having a duration of 1 to 5 ms and rarely exceeding 300 mV in amplitude. When brief spontaneous fibrillation potentials of this sort are observed firing regularly at two or three different locations (outside the end-plate zone) of a resting muscle, one may conclude that the fibers are denervated. Usually, fibrillation potentials discharge at an almost regular rate. In some early lesions (less than 6 to 8 weeks), irregularly firing fibrillation potentials may be observed.

Diseases such as poliomyelitis, which damage spinal motor neurons, or injuries of peripheral nerves or anterior spinal roots frequently produce only partial denervation of the involved muscles. In such muscles, one electrode placement may record fibrillation potentials at rest from denervated fibers and normal potentials during voluntary contraction from nearby healthy fibers. Fibrillation potentials continue until the muscle fiber is reinnervated by progressive proximal-distal regeneration of the interrupted nerve fiber or by the outgrowth of new axons from nearby healthy nerve fibers (collateral sprouting), or until the atrophied fibers degenerate and are replaced by connective tissue, a process that may take many years. In addition, fibrillation potentials may take the form of positive sharp waves, i.e., spontaneous, initially positive diphasic potentials of longer duration and slightly greater amplitude than the spikes of fibrillation potentials (see Fig. 45-7A).

Fibrillation potentials, while characteristic of neurogenic denervation, are not altogether specific; for example, they are seen in muscle diseases such as polymyositis and inclusion body myositis, which presumably damage the neural innervation to small regions of muscle or isolate segments of a muscle fiber from its end plate.

**Fasciculation Potentials** As stated earlier, a fasciculation is the spontaneous or involuntary contraction of a motor unit or part of a motor unit. Such contractions may cause a visible dimpling or twitching under the skin, though ordinarily they are of insufficient force to move a joint. Large distal fasciculations, however, can briefly displace a finger or toe; they occur irregularly and frequently, and prolonged inspection of the skin overlying a muscle may be necessary to detect them. The accompanying electrical form of an individual fasciculation potential is relatively constant. Typically, a fasciculation potential will have three to five phases (i.e., they are “polyphasic” as described later, in contrast to normal bi- or triphasic fibrillation potentials). A duration of 5 to 15 ms (longer than normal but somewhat less in the facial muscles), and an amplitude of several millivolts (see Fig. 45-7B). Fasciculation potentials are evidence of motor nerve fiber irritability, most often the result of reinnervation following nerve or motor neuron damage. Thus, the combination of fibrillations and fasciculations indicates active denervation combined with more chronic reinnervation of muscle; i.e., a long-standing but still ongoing process.

The precise source of fasciculation is still contested. Forster and colleagues, in the 1940s, challenged the original belief that the discharge originated in anterior horn cells by demonstrating that fasciculations persisted after nerve block in ALS and ceased only with the appearance of fibrillation potentials, signifying wallerian (axonal) degeneration. These observations favored a distal site of generation. Other physiological and pharmacological evidence pointed to the first segment of the motor axon, or to the distal axon, or even to the motor point (the site of insertion of the nerve into muscle), involving elements of the postsynaptic muscle membrane (particularly in the case of benign fasciculations) as the source of the spontaneous electrical activity. It seems that several regions of the axon are capable of spontaneous impulse generation, depending on the underlying disease. Most of the diseases that produce fasciculations involve the anterior horn cell or the motor root, but more
distal sites in the motor axon are active in cases of nerve compression and polyneuropathy.

Occasional fasciculation potentials—particularly in the calves, hands, and periorcular or paranasal muscles—occur in many normal persons. They can be almost constant for days or weeks on end, or even for years in some individuals, without weakness or wasting; therefore they need not be taken as evidence of disease (benign fasciculations). Certain quantitative features of fasciculations, such as brief duration and a consistent pattern and location of firing, favor benign over pathologic discharges. Shivering induced by low temperature and twitchings associated with low serum calcium levels are other forms of fasciculatory activity.

Fasciculation potentials occur with great frequency in chronic, slowly advancing, destructive diseases of the anterior horn cells, such as ALS and progressive spinal muscular atrophy. In these diseases, both voluntary MUPs and fasciculation potentials may be of long duration (more than 15 ms) and of increased amplitude, indicating chronic denervation and reinnervation. They are seen often in the early stages of poliomyelitis but only occasionally in the chronic phase of the disease, perhaps because the affected cells die rapidly. When anterior horn cells degenerate once again in older individuals who had had poliomyelitis (postpolio syndrome), fasciculations may return. Occasionally, they are seen in one muscle as a result of a compressive anterior root lesion, such as those caused by a protruded intervertebral disc; large numbers of axons may be affected, with the result that the fasciculations (or even cramps) may be more prominent than with disease of anterior horn cells. Fasciculation potentials in lesser numbers are also observed with chronic nerve entrapments, e.g., ulnar neuropathy at the elbow and other peripheral nerve lesions and some polyneuropathies. In all these cases, the damaged neuron or its axon seems to leave intact axons in a state of hyperirritability. The blocking of axon conduction by local anesthesia does not abolish the fasciculation, but curare-like drugs do so.

**Less Common Types of Spontaneous Electrical Activity (See Chap. 55)** One of these is myokymia (pages 1194 and 1278), a persistent quivering and rippling of muscles at rest ("live flesh"). The EMG picture is distinctive. The spontaneously firing MUPs are called myokymic potentials or discharges and consist of groups of repetitive discharging units, each firing at its own rate, quasi-rhythmically, usually several times per second, followed by an even briefer period of silence. The small motor unit discharges may occur singly or as doublets, triplets, or multiplets. The site of generation of this activity has also been contested, possibly because it may arise from several sites, but always the site is peripheral, not central, and is believed to correspond to an alteration in the calcium concentration in the microenvironment of the motor axon. Spontaneous discharges arising in large myelinated fibers have been implicated in the genesis of myokymia; indeed, demyelinating polyneuropathies are among the conditions that give rise to this phenomenon. Myokymia is also caused by peripheral nerve hyperexcitability due to both potassium channel mutations and antibodies against the channels. This activity may be blocked by lidocaine infusion around the peripheral nerve and may be diminished by carbamazepine or phenytoin.

In the syndrome of continuous muscle fiber activity or Isaacs syndrome (page 1278), which is actually a generalized form of myokymia, EMG discloses high-frequency (up to 300-Hz) repetitive discharges of varying waveforms.

Focal and segmental myokymias differ in small ways from the generalized form of myokymia with regard to the timing and duration of the discharges. The focal types refer mainly to facial myokymia, seen most often in multiple sclerosis, Guillain-Barré syndrome, large cerebellopontine angle tumors, or compression of the facial nerve by a small aberrant blood vessel, but it may follow any peripheral nerve injury and regeneration. The EMG patterns are complex, either high-frequency (30- to 100-Hz) recurrent bursts or brief lower-frequency bursts. Segmental myokymia is a common occurrence in radiation injuries of the brachial plexus. The EMG bursts tend to be longer and less frequent than in generalized myokymia, and the interburst frequency is highly variable. The origin of these discharges (also referred to as neuromyotonia) is probably in the distal peripheral nerve, where activity of afferent fibers, possibly via ephaptic transmission, irregularly excites distal motor terminals. Segmental myokymia refers to similar activity in the distribution of one or more adjacent motor roots. This activity persists during sleep and general anesthesia.

The phenomenon of myotonia, which denotes a failure of voluntary relaxation of muscle because of sustained firing of the muscle membrane (see pages 1265 and 1270), is characterized by high-frequency repetitive discharges generally having a positive sharp wave form. These myotonic discharges wax and wane in amplitude and frequency, producing a “dive-bomber” sound on the audio monitor. The discharges can be elicited mechanically by percussion of the muscle or movement of the needle electrode and are also seen following voluntary contraction or electrical stimulation of the muscle via its motor nerve. The MUPs may appear normal during voluntary contraction, but they are not followed by the silence that normally occurs on relaxation; instead, there is a “prolonged afterdischarge” consisting of long trains of fibrillation-like potentials that may take as long as several minutes to subside (Fig. 45-8A). These EMG findings can be seen with any myotonic disorder. If the muscle is activated repeatedly at short intervals, the late discharge becomes briefer and briefer and eventually disappears (see Fig. 45-8B), as the patient becomes able to relax the exercised muscle ("warm-up" effect). In the paradoxical myotonia

Figure 45-8. A. Myotonia congenita (Thomsen disease). The five lines are a continuous record of activity in the biceps brachii following a tap on the tendon. The initial response is within normal limits, but it is followed by a prolonged burst of rapid activity, gradually subsiding over a period of many seconds or minutes. B. Same electrode placement as in A. Response to the first of a series of tendon taps. “Warm-up” has occurred, and the characteristic prolonged myotonic activity is no longer evident. (See Chap. 54 for a description of the disease.)
These disorders are discussed in subsequent chapters. Some forms seem to involve changes in the chloride conductance.

Denny-Brown and Nevin, myotonia is generated by single muscle fibers, and the mechanism of the membrane instability, at least in Thompsen disease. As shown by the single-fiber EMG studies of Nielsen and colleagues have found a decreasing recruitment pattern and increasing activity after each of a succession of voluntary contractions. This is the converse of what happens in congenital myotonia. In the stiff-man syndrome, painful muscle spasms and stiffness are generated by a spinal mechanism; the EMG potentials resemble normal motor units but are abnormal by virtue of continuous firing at rest (see page 1279).

In the stiff-man syndrome, painful muscle spasms and stiffness are generated by a spinal mechanism; the EMG potentials resemble normal motor units but are abnormal by virtue of continuous firing at rest (see page 1279).

Abnormalities in Amplitude, Duration, and Shape of Motor Unit Potentials Figures 45-9 (schematically) and 45-10 depict the ways in which disease processes affect the motor unit and the appearance of the MUP in the EMG.

Motor Unit Potentials in Denervation Early in the course of denervation, many motor units with functional connections to the spinal cord are unaffected, and though the number of MUPs appearing during contraction is reduced, the configurations of the remaining ones are quite normal. In time, the remaining MUPs often increase in size and in electrical amplitude, perhaps two to three times normal, and become longer in duration and sometimes polyphasic (more than four phases). Such large and sometimes giant potentials (see Figs. 45-9C and 45-10B) are believed to arise from motor units containing more than the usual number of muscle fibers that are spread out over a greatly enlarged territory within the muscle. Presumably, new nerve twigs have sprouted from nodal points and terminals of undamaged axons and have reinnervated previously denervated muscle fibers, thus adding them to their own motor units. Soon after reinnervation, the MUPs generated will be low in amplitude, extremely prolonged, and polyphasic, findings that constitute a transitional configuration of early reinnervation. These amplitudes disappear as the motor unit is reestablished. Increased amplitude is usually associated with very chronic, proximal axon loss, e.g., with remote poliomyelitis and chronic cervical radiculopathy. These MUPs are to be differentiated from (1) polyphasic potentials of.

Abnormalities in Amplitude, Duration, and Shape of Motor Unit Potentials Figures 45-9 (schematically) and 45-10 depict the ways in which disease processes affect the motor unit and the appearance of the MUP in the EMG.

Motor Unit Potentials in Denervation Early in the course of denervation, many motor units with functional connections to the spinal cord are unaffected, and though the number of MUPs appearing during contraction is reduced, the configurations of the remaining ones are quite normal. In time, the remaining MUPs often increase in size and in electrical amplitude, perhaps two to three times normal, and become longer in duration and sometimes polyphasic (more than four phases). Such large and sometimes giant potentials (see Figs. 45-9C and 45-10B) are believed to arise from motor units containing more than the usual number of muscle fibers that are spread out over a greatly enlarged territory within the muscle. Presumably, new nerve twigs have sprouted from nodal points and terminals of undamaged axons and have reinnervated previously denervated muscle fibers, thus adding them to their own motor units. Soon after reinnervation, the MUPs generated will be low in amplitude, extremely prolonged, and polyphasic, findings that constitute a transitional configuration of early reinnervation. These amplitudes disappear as the motor unit is reestablished. Increased amplitude is usually associated with very chronic, proximal axon loss, e.g., with remote poliomyelitis and chronic cervical radiculopathy. These MUPs are to be differentiated from (1) polyphasic potentials of.
normal duration, which, as has been mentioned, make up as much as 10 percent of the total number of MUPs in normal muscle, and (2) polyphasic MUPs of short duration and low amplitude, which are characteristic of most myopathies and of myasthenia gravis and other disorders of neuromuscular transmission.

**The Motor Unit Potential in Myopathy**  Diseases such as polymyositis, the muscular dystrophies, and other myopathies that randomly destroy muscle fibers or render them nonfunctional obviously reduce the population of muscle fibers per motor unit, as shown in Fig. 45-9B. Therefore, when such a unit is activated, its potential is of lower voltage and shorter duration than normal, and it may also appear polyphasic as the compound MUP becomes fragmented into its constituent single-fiber potentials. Slowing of the propagated muscle fiber action potential in affected muscle fibers is also believed to contribute to the changes in the “myopathic” MUP. When most of the muscle fibers are affected, the MUPs are very small and of short duration and are recruited out of proportion to the tension generated—so-called increased recruitment. Both types of alterations produce a characteristic high-pitched crackling sound from the audio monitor that has been likened to rain falling on a tin roof. They occur in all forms of chronic myopathies. Identi cal MUP changes are seen occasionally with other processes that cause disintegration of the motor unit, e.g., early Guillain-Barré syndrome (due to conduction block along some of the terminal nerve fibers), and rarely with disorders of neuromuscular transmission (myasthenia gravis, other myasthenic syndromes), but they are most characteristic of primary muscle disease.

As mentioned earlier, fibrillation potentials, while typical of denervation, are sometimes seen in the myositides, inclusion-body myopathy, and the rapidly progressive muscular dystrophies, perhaps because of segmental necrosis of muscle fibers that isolates a segment of the fiber from its nerve supply. In myasthenia gravis, where transmission of impulse fails at the neuromuscular junction, a single MUP may vary in amplitude during sustained weak contraction and some fibers cease to function. Electromyographic recordings of single muscle fibers belonging to the same motor unit disclose varying interpotential intervals on successive discharges; this phenomenon is called “jitter” and increases to the point of actual block, with deficits in neuromuscular transmission within a motor unit (see below and Chap. 53).

**Abnormalities of the Interference Pattern**  Diseases that reduce the population of functional motor neurons or axons within the peripheral nerve decrease the number of motor units that can be recruited in the affected muscles. The decreased number of motor units available for activation then produce an incomplete interference pattern, which is manifest by a decreased number of units firing at a moderate to rapid rate. A severe reduction in the interference pattern may result in the recruitment of only a single unit (see Fig. 45-6B). Structural damage to nerve as well as demyelinating block can produce this pattern of reduced recruitment; indeed a reduced recruitment pattern coupled with the absence of denervation indicates a conduction block.

If muscle power is reduced in diseases such as polymyositis or muscular dystrophy, in which individual muscle fibers are affected, there may be little or no reduction in the number of motor units available for recruitment until the process is far advanced and entire MUPs have been lost due to random loss of all their constituent muscle fibers. Nonetheless, each motor unit will consist of fewer muscle fibers than normal, so more motor units must be activated to reach a certain degree of force. A modest effort can thus produce a full interference pattern despite marked weakness (increased recruitment). Because fewer muscle fibers are firing, the amplitude of the pattern will be reduced from normal. This type of full, highly complex interference pattern of less than usual amplitude in the face of dramatic weakness is the hallmark of myopathy (see Fig. 45-6C).

**Motor Unit Counting**  This experimental technique, developed by McComas and colleagues, estimates the size of motor units and is thus exquisitely sensitive to changes of denervation and reinnervation. It is carried out by applying a weak stimulus to a motor nerve or motor point and increasing it gradually as the evoked muscle response is recorded. Each quantal increase in the compound evoked response is presumed to be due to the addition of a single motor unit. In reinnervated muscles the additional units are reduced in number and are abnormally large. The technique is used mainly for the investigation of motor neuron disorders. When a normal number and configuration of motor units is found, it has been helpful in distinguishing benign fasciculations from those of serious diseases.

**Single-Fiber Electromyography (SF-EMG)**  This is a special technique for the recording of single-muscle-fiber action potentials and is used to measure fiber density and so-called jitter. Fiber density is an index of the number and distribution of muscle fibers within a motor unit. Jitter is the variability of the interpotential interval of successive discharges of two single-muscle-fibers belonging to the same motor unit. This phenomenon is due largely to the very slight variability of delay at the branch points in the distal axon and by synaptic delay at the neuromuscular junction. For this reason, SF-EMG is particularly useful in the detection of disorders of neuromuscular transmission, especially myasthenia gravis where it has found its main clinical use. Fiber density and jitter may, however, also be increased in neuropathic disorders that cause denervation with reinnervation. They are usually normal or only slightly increased in myopathic disorders.

Testing for jitter is carried out by having the patient voluntarily contract a muscle to the slightest degree possible in order to activate only one motor unit (requiring a great deal of cooperation by the patient) or by stimulating an intramuscular nerve twig (requiring great patience on the part of the examiner). The EMG needle is advanced until two muscle fibers from the same motor unit are recorded. If the oscilloscope sweep is triggered by the firing of the first fiber, a fluctuating latency of the second fiber potential can be seen on the screen as a movement (jitter) of the second peak. The degree of jitter can be quantitated by measuring the interval between the activation of the two muscle fibers (the rate of slightly differing lengths of the terminal axons) from which a mean interpeak interval is determined. Approximately 20 fiber pairs are sampled, and an average of the mean consecutive intervals can be derived. In a muscle such as the extensor digitorum communis, the average variation should be no more than 34 ms. The acceptable average is lower for large proximal muscles. Also, in disease of the neuromuscular junction one muscle fiber in a pair may fail to fire intermittently as a result of a blocking of conduction. Further details of this technique and its clinical applications are discussed fully by Stålberg and Trontelj.

**Imaging of Muscle and Nerve**

Imaging techniques—computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound—enable one to measure
muscle volume and to recognize qualitative changes in muscle structure (see review of deVisser and Reimers). Such methods are finding increasing clinical and research use in the diagnosis of disorders of muscle and in gauging the effects of treatment. CT scans of dystrophic muscle show foci of decreased attenuation, representing masses of fat cells. The fatty masses spread gradually from multiple foci and eventually replace muscle fibers. The original shape of the muscle is retained; indeed, an enlarged weak muscle containing mostly fat confirms the clinical impression of pseudohypertrophy. In denervative atrophy, the muscles are obviously small and contain multiple punctate areas of decreased attenuation, which represent interstitial fat. Eventually, large portions of chronically denervated muscle may be replaced by fat. Blood, blood products, and calcium deposits are expressed by increased attenuation in CT. This may be helpful in the diagnosis of muscle trauma, myositis ossificans, and polymyositis.

In MR images, fat and bone marrow have a high signal intensity, while fascia, ligaments, and cortical bone lack signal intensity. In T1-weighted images, normal muscle has a low signal and dystrophic muscle, a slightly increased signal; in T2-weighted images, dystrophic muscle has a slightly enhanced signal. Given its sensitivity to these dystrophic changes in muscle, MRI is particularly effective in determining the distribution of muscle involvement in a dystrophy. Transverse MR sections, for example, can help distinguish the topographic patterns of such disorders as the proximally predominant Becker dystrophy and the distally predominant Miyoshi myopathy or subtle subtypes of Emery-Dreifuss dystrophy (Mercuri). Spectroscopic MRI in metabolically determined myopathies has the capacity to quantitate levels of selected biochemical constituents of muscle, including intracellular pH and levels of metabolic intermediates such as phosphocreatine. This is particularly effective in demonstrating subnormal generation of intracellular acidosis after a limb is exercised in disorders of glycogenolysis and of glycolysis. Some individuals with mitochondrial disease of muscle will demonstrate rapid depletion of energy supplies and profound delays in recovery that can be quantified and used as an endpoint for treatments.

New magnetic resonance techniques are also being developed that allow the imaging of nerves. This may be an aid in traumatic nerve injury and in demonstrating neuromas, hypertrophy or atrophy of a nerve trunk, as well as neural tumors.

**BIOPSIES OF MUSCLE AND NERVE**

Muscle biopsy can be of great diagnostic value, but both surgical and microscopic techniques must be exacting. The muscle chosen for study should be accessible; there should be evidence that it has been affected but not totally destroyed by the disease in question; and it should not have been the site of a recent injection or EMG study, since the trauma of the needles produces focal necrotizing and inflammatory lesions. Muscle biopsy is helpful in distinguishing the following basic disorders in patients with neuromuscular disease.

**Muscle Biopsy**

1. **Denervation atrophy.** Reduction in the size of muscle fibers with an accompanying enlargement of intact motor units (due to collateral reinnervation) and degenerative changes in some fibers are the main changes of denervation atrophy. **Group atrophy** denotes enlarged motor units where all the fibers in the group are reduced to the same size; this is typical of progressive denervation. Normally, the fibers of each motor unit are not clustered, so that when grouping occurs it means that some fibers of a denervated unit have been adopted by an adjacent intact motor unit. This change typifies axonal neuropathies and many spinal cord diseases that affect the anterior horn cell. A related change is particularly well shown in histochemical stains for ATPase, phosphorylase, and oxidases, where the normal mosaic pattern of fiber types is altered. The use of these stains reveals fiber type grouping, the most specific histologic evidence of denervation and reinnervation. Here, muscle fibers of similar histochemical type form groups of 15 or more fibers as a result of reinnervation by a single motor neuron. The diagnosis of denervation atrophy can usually be made from the clinical and EMG examinations; seldom is biopsy necessary for this purpose, but it is still utilized in cases of possible ALS, for example, where the diagnosis remains uncertain after other testing.

2. **Segmental necrosis of muscle fibers with myophagia and various manifestations of regeneration.** These are the typical changes in idiopathic polymyositis (in combination with infiltrates of inflammatory cells), and infective polymyositis (in the presence of *Trichinella, Toxoplasma*). These changes may also be observed in more limited form in Duchenne and other rapidly progressive muscular dystrophies.

3. **Inflammation and vasculitis.** Lymphocytic infiltration of the endomysium is most characteristic of polymyositis and in dermatomyositis it may be predominantly perimysial. The lymphocytic infiltrate is often florid in these two processes, whereas it tends to be less intense in inclusion body myositis. Lesser degrees of inflammation are common in the myopathies associated with Sjögren syndrome, mixed connective tissue disease, and scleroderma. Numerous other processes—including the infections mentioned earlier and some dystrophies (especially the fascioscapulohumeral type)—may be associated with an inflammatory reaction. There is usually acute myofibrillar destruction in regions of maximal lymphocytic infiltration.

The muscle is a frequent site of inflammatory vascular destruction (vasculitis) in systemic diseases such as polyarteritis nodosa, and for this reason it is often useful to obtain a small sample of muscle adjacent to a nerve biopsy. The finding of a granulomatous myopathy may indicate the presence of systemic sarcoidosis.

4. **Alterations in the protein and histochemical composition of muscle fibers** may be shown by special stains for enzymes, glycogen, and structural proteins that are implicated in disease. For example, it has become possible to detect the absence or deficiency of specific structural proteins of the muscle membrane that define each of the muscular dystrophies: dystrophin, sarcoglycan, laminin, as discussed in Chap. 50. These tests require rapid freezing (in a cryostat) rather than formalin fixation. Also, a number of enzymatic deficiencies and intrafiber glycogen storage that lead to weakness and muscle fatigue may be detected by appropriate histochemical staining (Chap. 51).

5. **Unusual changes of muscle fibers.** Included here are sarcoplasmic masses and disorganized ring or serpentine collections of myofibrils and myofilaments (*Ringbinden*) in myo-
6. Abnormalities of mitochondria. Several distinctive abnormalities are readily visualized in muscle biopsies and are virtually diagnostic of an entire class of mitochondrial diseases. Light microscopy of frozen sections of muscle stained with the Gomori trichrome stain show the main feature, so-called ragged red fibers, which are accumulations of subsarcolemmal mitochondria.

7. Disorders of the neuromuscular junctions in which nerve fibers and muscle fibers appear to be intact. Here an abnormality may be revealed by performing the demanding procedure of motor point biopsy (to include the motor end plate), and using electron microscopy and special staining techniques for nerve terminals, cholinesterase, and the outlining of acetylcholine receptors. Myasthenia gravis, botulism, Lambert-Eaton syndrome, and myasthenic syndrome with motor end-plate cholinesterase deficiency fall into this category. Biopsy is rarely necessary for the diagnosis of these disorders but it has added considerably to our understanding of them.

As a rule, the muscle biopsy procedure requires no more than a small cleanly excised block of muscle, 1.0 to 2.0 cm, which is prevented from contracting by a clamp or by tying at full length to a tongue depressor. As an alternative to the standard surgical technique, percutaneous needle biopsies are now being done routinely in neuromuscular clinics and may be adequate for the diagnosis of certain muscle dystrophies and for their study over time and for a number of other muscle diseases and denervation atrophy. Unfortunately, the erratic distribution of lesions in many of the common disorders of muscle lessens the diagnostic yield of all types of biopsy, but in general the needle biopsy is less satisfactory than an open biopsy. The study of the muscle biopsy requires special care in removal, transport, and fixation techniques. These are discussed in detail by Engel.

Nerve Biopsy

Nerve biopsies are processed for study by conventional histologic methods and by thin-section phase and electron microscopy. These methods, sometimes supplemented by study of teased fiber preparations and immunologic studies, can provide valuable histopathologic data. With ordinary microscopy and staining, one may find evidence of focal inflammation, vasculitis, amyloidosis, leprosy, or sarcoid. These procedures are most valuable in the diagnosis of inflammatory, vasculitic, and amyloid neuropathies. In children, the nerve biopsy may reveal the histologic features of metachromatic or globoid leukodystrophy, giant axonopathy, or neuroaxonal dystrophy. However, nerve biopsy is relatively unhelpful in most other polyneuropathies and should be used prudently because the procedure is not without complications, such as the occasional occurrence of wound infections, painful stump neuromas, persistent dysesthesias of the lateral foot or heel, and thrombophlebitis. Indeed, in a prospective study of 50 consecutive cases with sural nerve biopsy reported by Gabriel and colleagues, nerve biopsy served only to confirm the clinical diagnosis in 70 percent of cases and altered the diagnosis in only 14 percent. Nevertheless, in some instances of idiopathic polynuropathy that are not clarified by clinical and electrophysiologic testing, and particularly if a treatable chronic inflammatory polyneuropathy is suspected, many neuromuscular experts resort to sural nerve biopsy as a final diagnostic step. Although the sural nerve is typically chosen for biopsy, the superficial peroneal nerve and the adjacent peroneus brevis muscle gives a higher yield in cases of vasculitis (see Collins et al).

In diseases that involve only the motor nerves, it is sometimes useful to sample a fascicle of the superficial radial nerve or the nerve to the extensor digitorum brevis, which may be taken with the muscle itself. Chronic inflammatory neuropathy and vasculitic neuropathy may be disclosed by this type of biopsy when the sural nerve is unaffected. Also, in selected circumstances we have undertaken biopsy of small radicles of upper lumbar roots (L1 or L2) to establish the diagnosis of an infiltrative lymphoma. Little deficit occurs from the removal of nerves from these alternative sites if the procedure is done by an experienced surgeon.

Additional techniques that are utilized in the study of muscle biopsies and specific pathologic findings that characterize the many individual diseases, of both muscle and peripheral nerve, are discussed in the chapters that follow.

Other Laboratory Tests in the Study of Muscle and Nerve Disease

None of the diagnostic procedures previously described may be taken as an infallible diagnostic index of a specific disease of muscle or nerve. Each procedure is subject to technical error and the findings to misinterpretation. A biopsy specimen may be taken from an unaffected muscle or portion of a muscle, and such a sampling error causes the sample to be normal in the face of obvious clinical evidence of disease. This is particularly true of the inflammatory myopathies that affect muscle in heterogeneous and spotty manner.

Rough excision and improper fixation and staining may produce artifacts that may be misinterpreted as marks of disease when, in fact, the muscle (and nerve) is microscopically normal. Similarly, EMG study may fail to record fibrillations in obviously denervated muscle, particularly in slowly progressive disorders. Also, in some of the muscles of the feet, fibrillations and fasciculations may be found in normal asymptomatic older individuals (Falck and Alaranta). As in the study of all disease, laboratory data have significance only if evaluated in the light of the clinical findings.

CHAPTER 46

DISEASES OF THE PERIPHERAL NERVES

In this single chapter, an attempt is made to provide an overview of the very large and difficult subject of peripheral nerve disease. Since the structure and function of the peripheral nervous system are relatively simple, one might suppose that our knowledge of its diseases would be complete. Such is not the case. For example, when a group of patients with chronic polyneuropathy were investigated intensively in a highly specialized center for the study of peripheral nerve diseases several decades ago, a suitable explanation for their condition could not be found in 24 percent (Dyck et al., 1981) and only slightly less discouraging figures prevail in our clinics today. Moreover, the physiologic basis of many neuropathic symptoms continues to elude experts in the field, and in many of the neuropathies the pathologic changes have not been fully determined.

There has, however, been a recent surge of interest in diseases of the peripheral nervous system, which promises to change this state of affairs. Electron-microscopic studies, new quantitative histometric methods, and refined physiologic techniques have already expanded our knowledge of the structure and function of peripheral nerves, and rapidly advancing techniques in the fields of immunology and molecular genetics are beginning to clarify entire categories of neuropathic disease. Also, in recent years, effective forms of treatment for several peripheral neuropathies have been introduced, making accurate diagnosis imperative. For these reasons, clinicians now find the peripheral neuropathies among the most challenging and gratifying categories of neurologic disease.

GENERAL CONSIDERATIONS

It is important to have a clear concept of the extent of the peripheral nervous system (PNS) and the mechanisms whereby it can be affected by disease. The PNS includes all neural structures lying outside the pial membrane of the spinal cord and brainstem with the exception of the optic nerves and olfactory bulbs, which are but special extensions of the brain. The parts of the PNS within the spinal canal and attached to the ventral and dorsal surfaces of the cord are called the spinal nerve roots; those attached to the ventrolateral surface of the brainstem are the cranial nerve roots, or just cranial nerves.

The dorsal or posterior (afferent or sensory) roots consist of central axonal processes of the spinal sensory ganglia and the cranial ganglia. On reaching the spinal cord and brainstem, they extend for variable distances into the dorsal horns and posterior columns (funiculi) of the cord and into the spinal trigeminal and other tracts in the medulla and pons before synapsing with secondary neurons as described in Chap. 9. The peripheral axons of the dorsal root ganglion cells are the sensory nerve fibers. They terminate as freely branching or specialized corpuscular endings—i.e., the sensory receptors—in the skin, joints, and other tissues. The sensory nerve fibers vary greatly in size and in the thickness of their myelin covering; based on these dimensions, they are classified as type A, B, or C as discussed in Chap. 8. The ventral, or anterior (efferent, or motor), roots are composed of the emerging axons of anterior and lateral horn cells and motor nuclei of the brainstem. Large, heavily myelinated fibers terminate on muscle fibers and smaller unmyelinated ones terminate in sympathetic or parasympathetic ganglia. From these autonomic ganglia issue the axons that terminate in smooth muscle, heart muscle, and glands. Traversing the subarachnoid space, where they lack well-formed epineurial sheaths, the cranial and spinal roots (both sensory and motor) are bathed in and are susceptible to substances in the cerebrospinal fluid (CSF), the lumbar sacral roots having the longest exposure (Fig. 46-1).

The vast extent of the peripheral ramifications of cranial and spinal nerves is noteworthy, as are their thick protective and supporting sheaths of perineurium and epineurium and their unique vascular supply through longitudinal arrays of richly anastomosing nutrient arterial branches that run in the epineurium and perineurium. The perineurium comprises the connective tissue sheaths that surround and separate each bundle of nerve fibers (fascicles) of varying size, each fascicle containing several hundred axons. The sheath that binds and surrounds all the fascicles of the nerve is the epineurium. As the nerve root approaches the cord, the epineurium blends with the dura (see Fig. 46-1). The fine connective tissue covering of individual nerve fibers is the endoneurium. The nerves traverse narrow foramina (intervertebral and cranial) and a few pass through tight channels peripherally in the limbs (e.g., the median nerve between the carpal ligament and tendon sheaths of flexor forearm muscles; the ulnar nerve in the cubital tunnel). These anatomic features explain the susceptibility of certain nerves to compression and entrapment and also to ischemic damage. The axons themselves contain a complex internal microtubular apparatus for maintaining the integrity of their membranes and for transporting substances such as neurotransmitters over long distances between the nerve cell body and the distant reaches of the nerve fiber.

Nerve fibers (axons) are coated with short segments of myelin of variable length (250 to 1000 μm), each of which is enveloped by a Schwann cell and its membrane. Indeed, the Schwann cell membrane surrounding an axon is the myelin sheath. In fact, the PNS may be accurately defined as the part of the nervous system that is invested by the cytoplasm and membranes of the Schwann cells. Each myelin segment and Schwann cell has a symbiotic relationship to the axon but is always morphologically independent. The structure of the axonal membrane in the gaps between segments of the myelin sheaths (nodes of Ranvier) is specialized, containing a high concentration of sodium channels and permitting the saltatory electrical conduction of nerve impulses, as described in Chap. 45. Unmyelinated fibers, more numerous in peripheral nerves than myelinated ones, also arise from cells in dorsal root and autonomic ganglia. Small bundles of these naked (unmyelinated) axons are enveloped by a single Schwann cell; delicate tongues of Schwann cell cytoplasm partition these bundles and separate individual axons. Each sensory nerve fiber terminates in a specialized ending which is designed to be especially sensitive to certain natural stimuli as discussed in Chaps. 8 and 9.
Pathogenic Mechanisms in Peripheral Nerve Disease

The anatomic features previously mentioned enable one to conceptualize the possible avenues by which disease may affect the peripheral nerves. Pathologic processes may be directed at any one of the several groups of nerve cells whose axons constitute the nerves, i.e., the cells of the anterior or lateral horns of the spinal cord, the dorsal root ganglia, or sympathetic and parasympathetic ganglia. Each of these cell types exhibits specific vulnerabilities to disease processes, and if destroyed—as, for example, the motor nerve cells in poliomyelitis—there results a secondary degeneration of the axons and myelin sheaths of the peripheral fibers of these cells. Neuropathic symptoms may also be induced by alterations of function and structure of the ventral and dorsal columns of the spinal cord, which contain the fibers of exit and entry of anterior horn and dorsal root ganglion cells, respectively. The myelin of these centrally located fibers is constituted differently from that of the peripheral nerves, being enveloped by oligodendrocytes rather than Schwann cells, and the fibers are supported by astrocytes rather than fibroblasts.

Because of the intimate relation of the nerve roots to the CSF and to specialized arachnoidal cells (the arachnoidal villi), a pathologic process in the CSF or leptomeninges may damage the exposed spinal roots. Disease of the connective tissues may affect the peripheral nerves that lie within their sheaths. Diffuse or localized arterial diseases may injure nerves by occluding their nutrient arteries. In a large category of immune-mediated neuropathies, damage is the result of a cellular or humoral attack on various components of myelin. A subset of these is characterized by the binding of circulating antibodies to the specialized regions at the nodes of Ranvier, causing a block of electrical conduction. Also, a complement-dependent, humoral immune reaction against the radicular or peripheral axon is known. Toxic or immunologic agents that selectively damage the Schwann cells or their membranes, cause demyelination of peripheral nerves leaving axons relatively intact, or a toxin may specifically affect axons by poisoning their cell bodies, the axolemma, or the lengthy and complex axonal transport apparatus. Finally, one might correctly suppose that axons of the motor or sensory nerves, sympathetic fibers of varying diameter and length, or the end organs to which they are attached would each have its own particular liability to disease.

Some of this is theoretical and somewhat speculative. At present we can cite only a few examples of diseases or toxins that cause disease through these mechanisms exclusively: e.g., diphtheria, in which the bacterial toxin acts directly on the membranes of the Schwann cells near the dorsal root ganglia and adjacent parts of motor and sensory nerves (the most vascular parts of the peripheral nerve); polyarteritis nodosa, which causes widespread occlusion of vasa nervorum, resulting in multifocal nerve infarction; tabes dorsalis, in which there is a treponemal meningoradiculitis of the posterior roots (mainly of the lumbosacral segments) that lie next to the arachnoidal villi where CSF is resorbed; doxorubicin intoxication, wherein protein synthesis of dorsal root ganglion cells is blocked, with subsequent neuronal destruction; poisoning with arsenic, which combines with the axoplasm of the largest sensory and motor nerves via sulfhydryl bonds; and vincristine toxicity, which damages the microtubular transport system. Analogous anatomic pathways are probably implicated in other diseases by mechanisms that remain to be discovered.

Among the genetically determined neuropathies, the altered gene products are now known in some cases to lead to defective myelination, which greatly slows conduction along nerves. In other genetic diseases it is speculated that structural components of the axon are disrupted, leading to axonal degeneration and impaired electrical conduction.

Pathologic Reactions of Peripheral Nerve

Pathologically, several distinct processes are recognized in the peripheral nerve, although they are not disease-specific and may be present in varying combinations in any given case. The classic ones are segmental demyelination, wallerian degeneration, and axonal degeneration (diagrammatically illustrated in Fig. 46-2).

The myelin sheath is the most susceptible element of the nerve fiber, for it may break down as part of a primary process involving the Schwann cells or the myelin sheath itself, or it may be damaged secondarily, as a consequence of disease affecting its axon. Focal degeneration of the myelin sheath with sparing of the axon is called
**Figure 46-2.** Diagram of the basic pathologic processes affecting peripheral nerves. In wallerian degeneration, there is degeneration of the axis cylinder and myelin distal to the site of axonal interruption (arrow), and central chromatolysis. In segmental demyelination, the axon is spared. In axonal degeneration, there is a distal degeneration of myelin and axis cylinder as a result of neuronal disease. Both wallerian and axonal degeneration cause muscle atrophy. Further details in text. (Courtesy of Dr. Arthur Asbury.)

**segmental demyelination.** The characteristic change of segmental demyelination is the disappearance of the sheath over segments of variable length, bounded on each end by a preserved segment of myelin. This exposes long segments of the axon to the interstitial environment. Myelin may also degenerate secondary to axonal disease in a general process that may occur either proximal or distal to the site of axonal interruption. Common to many lesions of the peripheral nerve is the type of reaction of both the axon and myelin called **wallerian degeneration.** Wallerian degeneration might be described as “dying forward,” a process in which the nerve degenerates from the point of axonal damage outward. In contrast, when the axon degenerates as part of a “dying-back” phenomenon in a more generalized metabolically determined polyneuropathy, it is termed **axonal degeneration.** Here, the axon is affected from the distal-most site to the proximal, with dissolution of myelin that occurs in parallel with the axonal change. One possible explanation for this process is that the primary damage is to the neuronal perikaryon, which fails in its function of synthesizing proteins and delivering them to the distal parts of the axon. There is also the possibility that certain toxic and metabolic processes affect axons uniformly along their length or impair anterograde axonal transport to the periphery; the functional impairment would then be proportional to the size and length of the blocked axons.

Destruction of an anterior horn cell or proximal motor root results in a gradual dissolution of the distal motor nerve and its myelin sheath (a form of wallerian degeneration). Similar destruction of the dorsal root produces a secondary wallerian degeneration of the posterior columns of the spinal cord, but not of the peripheral sensory nerve since the dorsal root ganglion cells maintain the integrity of the distal axon. In other words, destruction of axons results within several days in a wallerian degeneration of all the myelin distal to the point of injury. The myelin breaks down into blocks or ovoids in which lie fragments of axons (digestion chambers of Cajal). The myelin fragments are then converted, through the action of macrophages, into neutral fats and cholesterol esters and carried by these cells to the bloodstream.

Certain diseases affect the neuron primarily rather than the axon and cause either a motor or sensory **neuronopathy.** In the former case the anterior horn cell is affected by a disease process (motor neuron disease, or motor neuronopathy), and in the latter, the sensory ganglion cell (ganglionopathy) is destroyed. Degeneration of the respective nerve fibers follows.

These pathologic reactions are more easily understood if one considers certain features of cytoskeletal structure and function of nerve cells and their axons. The axon contains longitudinally oriented neurofilaments and microtubules, which are separated but interconnected by cross-bridges. Their main function involves the transport of substances from nerve cell body to axon terminal (anterograde transport) and from the distal axon back to the cell body (retrograde transport). Thus, when the axon is severed, organelles cannot be transmitted to the distal axon for the purpose of renewing membrane and neurotransmitter systems. By means of retrograde axonal transport, the cell bodies receive signals to increase their metabolic activity and to produce growth factors and other materials needed for axonal regeneration. In some incompletely defined way the axon creates a local environment that allows the Schwann cell to maintain the integrity of the adjacent myelin sheath. Loss
of this trophic signal leads to dissolution of the sheath, but not of the Schwann cell itself.

There are also highly characteristic histopathologic changes in the nerve cell body termed chromatolysis or axonal reaction that are a secondary consequence of axonal interruption. These retrograde changes consist of swelling of the cell cytoplasm and marginalization and dissolution of the Nissl substance. The important point is that despite the destructive changes in the nerve fibers, the nerve cells, while altered in histologic appearance, are left intact and reactive.

In segmental demyelination, recovery of function may be rapid because the intact but denuded axon needs only to become remyelinated. The newly formed internodal segments are initially thinner than normal and of variable length. By contrast, recovery is much slower with wallerian or axonal degeneration, often requiring months to a year or more because the axon must first regenerate and then reinnervate the muscle, sensory organ, blood vessel, etc., before function returns. When the regenerating axon first becomes myelinated, the internodal myelin segments are short, the length of one normal internode being replaced by three or four shorter new ones. Recurrent demyelination and remyelination lead to “onion bulb” formations and enlargement of nerves, the result of proliferating Schwann cells and fibroblasts that encircle the axon and its thin myelin sheath. If nerve cells are destroyed, no recovery of function is possible except by collateral regeneration from axons of intact nerve cells.

In the most extreme circumstances, interruption of a nerve by severing or crude destruction, the continuity is interrupted and may not be reestablished. Regenerating axonic filaments take aberrant courses and, with fibroblastic scar formation at the end of the central portion of the interrupted nerve, they form a pseudoneuroma.

These relatively few pathologic reactions cannot in themselves differentiate the hundred or more diseases of the peripheral nerves; but when they are considered in relation to the selective effects on various types and sizes of fibers, the topography of the lesions, and the time course of the process, they furnish criteria whereby many diseases can be distinguished. Moreover, the identification of these basic reactions of nerve is of great value in the inspection of pathologic material obtained from biopsy or autopsy.

There are in addition special pathologic changes, not specifically neural in nature, that characterize certain diseases of the peripheral nervous system. These involve inflammatory or vascular changes or deposition of material in the interstitium of the nerve. For example, acute demyelinative polyneuritis of the Guillain-Barré type is characterized by endoneurial infiltrations of lymphocytes and other mononuclear cells in the nerves, roots, and sensory and sympathetic ganglia; frequently the infiltrates and destruction of myelin have a perivascular distribution. In polyarteritis nodosa, a characteristic necrotizing panarteritis with thrombotic occlusion of vessels and focal infarction of peripheral nerves are the dominant findings. Deposition of amyloid in the endoneurial connective tissue and walls of vessels affecting the nerve fibers secondarily by a toxic effect are the distinctive features of inherited and acquired amyloid polyneuropathy. In one of the inherited polyneuropathies of childhood, the axons are enlarged by tightly packed masses of neurofilaments. Diphtheritic polyneuropathy is typified by the predominantly demyelinative character of the nerve fiber change, the location of this change in and around the roots and sensory ganglia, the subacute course, and the lack of inflammatory reaction. Other polyneuropathies (paraneoplastic, nutritional, porphyric, arsenical, and uremic) are topographically symmetrical and all represent forms of axonal degeneration but at the present time cannot be distinguished from one another on histopathologic grounds. A number of neuropathies are characterized by the deposition of antibodies and complement on the myelin sheath or on elements of the axon. These changes can be demonstrated by immunohistopathologic techniques.

Concerning the pathology of the mononeuropathies, our knowledge is somewhat more complete. Compression of nerve or nerve roots, producing local or segmental ischemia, stretch, and laceration of nerves are understandable mechanisms, and their pathologic changes have been reproduced experimentally. Tumor infiltration and vasculitis with ischemic infarction of nerve account for some cases. Of infections and granulomas localized to single nerves, only leprosy, sarcoid, and herpes zoster represent identifiable disease states. For most of the acute mononeuropathies, the pathologic changes have yet to be defined, since they are usually benign reversible states that provide no opportunity for complete pathologic examination.

**SYMPTOMATOLOGY OF PERIPHERAL NERVE DISEASE**

There are a number of motor, sensory, reflex, autonomic, and trophic symptoms and signs that are more or less typical of peripheral nerve disease. Grouping them into syndromes based on their temporal and topographic features has proved to be of value in clinical diagnosis. The topographic patterns are detailed further on under “Approach to the Patient with Peripheral Neuropathy.” Here the primary symptoms of peripheral nerve disease are described.

**Impairment of Motor Function** Persistent impairment of motor function over days, weeks, or months in a topographic pattern that implicates peripheral nerves, signifies either segmental demyelination, axonal interruption, or destruction of motor neurons. The degree of weakness is proportional to the number of axons or motor neurons affected, although pain and kinesthetic loss may add to the functional impairment.

**Polyneuropathies** are generally marked by a symmetric distribution of the weakness or paralysis. In cases of diffuse axonal damage, the muscles of the feet and legs are affected earlier and more severely than those of the hands and forearms. In milder forms of axonal disease, only the feet and lower legs are involved. Truncal and cranial muscles are usually the last to yield, and then only in severe cases. This represents the “length dependent” pattern of axonal degeneration. The nutritional, metabolic, and toxic neuropathies assume the more common, predominantly distal, axonal pattern. The pathologic changes in such cases begin in the far distal parts of the largest and longest nerves and advance along the affected fibers toward their nerve cell bodies (dying-back neuropathy, “distal axonopathy”).

The typical distally predominant pattern is not generally found in the acute and chronic demyelinating inflammatory neuropathies, where the multifocal nature of lesions and blockage of electrical conduction leads to weakness of proximal limb and facial muscles before or at the same time as distal parts are affected. Another exception to the pattern of distally predominant weakness is porphyria, an axonal process in which there may be mainly proximal weakness.

Another characteristic pattern of neuropathic weakness is one in which all the muscles of the limbs, trunk, and neck are involved,
of generalized paralysis include diphtheria, tick paralysis, and certain toxic polyneuropathies. Fatalities, when they occur, are usually due to respiratory failure.

A predominantly bibrachial paralysis is an unusual presentation of neuropathic disease but may occur in the inflammatory-demyelinating polyneuropathies as well as in the Sjögren syndrome, chronic immune or paraneoplastic neuropathies, lead neuropathy, Tangier disease, and from familial brachial neuritis. (A more frequent cause of bibrachial palsy is disease of the motor neurons themselves, specifically, motor system disease, as discussed on page 939 or a lesion placed centrally in the cervical cord that damages these same neurons.) Paraparesis is not typical of the generalized polyneuropathies, but may be observed with infections and inflammations of the cauda equina, as occurs with Lyme disease, cytomegalovirus, herpes simplex, and with neoplastic nerve root infiltrations. Bifacial and other cranial nerve paralyses are likely to occur in GBS, with neoplastic invasion, and also with connective tissue diseases, human immunodeficiency virus (HIV) and herpes virus infection, sarcoidosis, Lyme disease, or one of the rare metabolic neuropathies (Refsum, Bassen-Kornzweig, Tangier, and Riley-Day). These are discussed in Chap. 47 on diseases of the cranial nerves and in respective chapters on infections and metabolic diseases of the nervous system.

Atrophy of weak or paralyzed muscles is highly characteristic of disease of the motor neuron or motor axon. It proceeds slowly over several months, the degree being proportional to the number of damaged motor nerve fibers. The maximum degree of denervation atrophy occurs in 90 to 120 days and reduces muscle volume by 75 to 80 percent. Atrophy may also be a consequence of disuse; it occurs over many weeks but in itself does not reduce muscle volume by more than 25 to 30 percent. Atrophy, therefore, does not coincide with or correspond to acute paralysis and is least prominent in the acute demyelinating neuropathies in which the nerve fiber is relatively less affected than is the myelin. In chronic axonal neuropathies, the degrees of paralysis and atrophy tend to correspond. Ultimately there is degeneration and loss of the denervated muscle fibers. This process begins in 6 to 12 months; in 3 to 4 years, most of the denervated fibers will have degenerated. If reinnervation takes place within a year or so, motor function and muscle volume may be restored.

**Tendon Reflexes** The rule is that diminution or loss of tendon reflexes is invariably a sign of peripheral nerve disease (an exception is areflexia in spinal shock described in Chap. 44). In the small-fiber neuropathies, however, tendon reflexes may sometimes be retained, even with marked loss of perception of painful and thermal stimuli and loss of autonomic function. This discrepancy is attributable to the fact that the afferent arc of the tendon reflexes utilizes the large, heavily myelinated fibers that originate in muscle spindles. Conversely, in neuropathies that affect the largest diameter, heavily myelinated fibers, the tendon reflexes are diminished early and out of proportion to weakness. Slowing of conduction in sensory fibers may also abolish the reflex by dispersing the afferent volley of impulses initiated by the tendon tap. There is generally a concordance between areflexia and a loss of proprioceptive and joint-position senses; i.e., the large nerve fibers from spindle afferents are of the same type and size as those mediating these forms of sensation. Furthermore, loss of sensory functions that are dependent on these large fibers in the presence of preserved reflexes implicates the central projections of the sensory ganglion cells i.e., a lesion in the posterior columns of the spinal cord. Regional loss of a reflex is usually a sign of a radiculopathy.

**Sensory Loss** (See also pages 138 to 142) Most polyneuropathies cause impairment of both motor and sensory functions, but one may be affected more than the other. In most of the toxic and metabolic neuropathies, sensory loss exceeds weakness; and in sensory neuronopathy, there is no motor deficit. By contrast, in GBS paralysis is more prominent than sensory loss. These differences are emphasized in the descriptions of individual peripheral nerve diseases in the later parts of the chapter.

In the polyneuropathies, sensation is affected symmetrically in the distal segments of the limbs, and more in the legs than in the arms. In most types, all sensory modalities (touch-pressure, pain and temperature, vibratory and joint position senses) are impaired or eventually lost, although one modality may be affected out of proportion to the others, or superficial sensation may be impaired more than deep sensation. Vibratory sense is often affected more than position and tactile senses. In extreme cases, as the neuropathy worsens, there is spread of sensory loss from the distal to more proximal parts of the limbs and, eventually, to the anterior abdomen, thorax, and face. An “escutcheon” pattern of sensory loss over the abdomen and thorax in severe axonal neuropathy may be mistaken for the sensory level of a spinal cord lesion. Another characteristic form of sensory loss affects the trunk, scalp, and face; this is the pattern of a sensory ganglionopathy that is the result of simultaneous affection of distal and proximal parts of the sensory nerve.

A pattern that is the converse of the large fiber sensory may be manifest in some diseases—namely, a loss of pain and temperature sensation with either sparing or lesser impairment of touch-pressure, vibratory, and position senses. This pattern resembles the dissociated sensory disturbance of syringomyelia (pages 140 and 1084). In some types of polyneuropathy it may be found predominantly in the lumbosacral region (it was originally referred to as “lumbosacral syringomyelia”). This “pseudosyringomyelic” dissociation of sensation may extend over the arms, trunk, and even cranial surfaces. Thévenard was the first to question its spinal basis, and it is now generally agreed that most such examples are due to hereditary or certain acquired small-fiber sensory neuropathies (amyloidosis, toxins such as chemotherapy, in congenital absence of pain, Riley-Day syndrome, and Tangier disease). Exceptionally, as in one of the families studied by Adams and associates, all forms of sensation may be lost over the entire body, while motor power and autonomic functions are preserved. Most often, universal sensory loss is attributable to an acquired disease affecting the sensory ganglia (sensory neuronopathy); usually this is a paraneoplastic process, but certain toxic or immune diseases do the same (e.g., Sjögren disease, scleroderma).

**Paresthesias, Pain, and Dysesthesias** These sensory symptoms have been described in Chap. 9. They tend to be especially marked in the hands and feet. “Pins and needles,” stabbing, tingling, prickling, electrical, and “Novocain-like” feeling, are the adjectives chosen by patients to describe these abnormalities. In some sensory neuropathies paresthesias and numbness are the only demonstrable features; objective sensory loss is lacking. Certain neuropathies cause pain, which may be described as burning, aching, sharp and cutting, or crushing, and at times may resemble the lightning pains of tabes dorsalis. Perversion of sensation (allodynia) is common-
place—e.g., tingling, burning, stabbing pain, or just an uncomfortable dysesthesia is induced by tactile stimuli. Under these conditions, a given stimulus induces not only an aberrant sensation but also one that radiates and persists after the stimulus is withdrawn. As remarked on pages 118 and 133, the patient’s reaction may seem to indicate a hypersensitivity ("hyperesthesia"), but more often the sensory threshold is actually raised and it is the sensory experience or response that is exaggerated (hyperpathia).

Painful paresthesias and dysesthesias are particularly common in certain types of diabetic, alcoholic-nutritional, and amyloid neuropathies. Mainly they affect the feet ("burning feet") and less often the hands. In herpes zoster they are confined to limited regions of the body. They may be a prominent feature in some cases of diabetic and other types of vascular neuropathy, and in a fairly common sensory neuropathy of obscure nature in elderly individuals. A particularly intense form of burning pain typifies the causalgia of a partial nerve lesion (usually traumatic) of the ulnar, median, posterior tibial, peroneal, or occasionally some other nerve (pages 120 and 1172).

The mechanism of thermal and painful dysesthesias is not fully understood. It has been theorized that a loss of large touch-pressure fibers disinhibits the pain-receiving nerve cells in the posterior horns of the spinal cord. An argument against this explanation is the lack of pain in Friedreich ataxia, in which the larger neurons degenerate, and also in certain purely sensory polyneuropathies, where only the perception of tactile stimuli (large fibers) is lost. A more likely explanation, supported by microneurographic recordings, is that dyesthetic pain results from autogenic ectopic discharges arising at many sites along surviving intact or regenerating nociceptive nerve fibers or their terminal receptors. In contrast to dyesthetic pain, it has been postulated, on uncertain grounds, that the deep, aching neuropathic pain of sciatica or brachial neuritis (nerve trunk pain) arises from irritation of the normal endings (nervi nervorum) in the sheaths of the nerve trunks themselves (Asbury and Fields). These considerations are discussed in Chap. 8.

Sensory Ataxia and Tremor Proprioceptive deafferentation with retention of a reasonable degree of motor function may give rise to ataxia of gait and of limb movement, as discussed in Chap. 9. Probably, dysfunction of the spino-cerebellar fibers of the peripheral nerves is the source of the ataxia. Some of the most severe ataxias of this type occur with sensory ganglionopathy, as commented further on.

Ataxia without weakness is characteristic of tabes dorsalis, a purely posterior root affection, but this syndrome can be essentially duplicated by diabetic polyneuropathy, which affects posterior roots as well as nerves (diabetic pseudotabes), and by a variant of the GBS (Fisher syndrome) as well as by certain sensory neuronopathies (ganglionopathies). While the ataxia in some instances is indistinguishable from that caused by cerebellar disease, other features of cerebellar dysfunction such as dysarthria and nystagmus are, of course, lacking. In the chronic sensory neuropathies with ataxic features, all movements, though strong, are rendered ineffective by virtue of the deep sensory loss. Characteristic of the sensory (tabetic) ataxic gait are brusque, flinging, slapping movements of the legs. Loss of proprioception may also give rise to small wavering, fluctuating movements of the outstretched fingers—called pseudoathetosis, or “dancing fingers.”

An action tremor of fast-frequency type may also appear during certain phases of a polyneuropathy. Shahani and coworkers had the impression that it is due to loss of input from the muscle-spindle afferents. Corticosteroid therapy enhances this fast tremor. A particularly severe form of slower tremor is combined with clumsiness of movement in certain neuropathies that affect large afferent fibers, specifically in the autoimmune, antemyelin-associated glycoprotein (MAG) polyneuropathy and in some cases of chronic inflammatory demyelinating polyneuropathy (CIDP). During action, the tremor may at times be so coarse as to resemble the intention tremor of cerebellar disease.

Deformity and Trophic Changes In a number of chronic polyneuropathies, the feet, hands, and spine become deformed. This is most apt to occur when the disease begins during childhood. Austin pointed out that foot deformity is found in 30 percent of patients with hereditary polyneuropathy, and spine curvature in 20 percent. In early life, the feet are pulled into a position of talipes equinus (plantar deviation) because of the disproportionate weakness of the pretibial and peroneal muscles and the unopposed action of the calf muscles. Atrophic paralysis of the intrinsic foot muscles while the bones are forming allows the long extensors of the toes to dorsiflex the proximal phalanges and the long flexors to shorten the foot, heighten the arch, and flex the distal phalanges. The result is the claw foot—le pied en griffe or pes cavus (high arches) when the process is less severe. These changes in the foot are valuable diagnostic indicators that a neuromuscular disease originated in early childhood or during intrauterine development. A congenital claw hand has a similar basis. In early childhood, unequal weakening of the paravertebral muscles on the two sides of the spine leads to kyphoscoliosis.

Denervation atrophy of muscle can be considered the main trophic disturbance resulting from interruption of the motor nerves. However, there are numerous other changes. In particular, analgesia of distal parts makes them susceptible to burns, pressure sores, and other forms of injury that are easily infected and heal poorly. In an anesthetic and immobile limb, the skin becomes tight and shiny, the nails curved and ridged, and the subcutaneous tissue thickened (“trophic changes”). Hair growth is diminished in denervated areas. If the autonomic fibers are interrupted, the limb is warm and pink. Repeated injuries and chronic subcutaneous and osteomyelitic infections may result in a painless loss of digits and the formation of plantar ulcers (mal perforant du pied). These are prominent features of the recessive form of hereditary sensory neuropathy, and we have observed them in dominant forms as well. In tabes dorsalis and syringomyelia as well as certain familial and other chronic polyneuropathies, analgesic joints, when chronically traumatized, may first become deformed and then actually disintegrate in a process called Charcot arthropathy (Charcot joint).

The pathogenesis of the trophic changes is not fully understood. Apart from analgesia, a critical factor may be inappropriate neural regulation of the distal vasculature, which interferes with normal tissue responses to trauma and infection. Ali and colleagues relate the ulcer formation to loss of C fibers, which mediate both pain and autonomic reflexes. However, paralyzed limbs, even in hysteresis, if left dependent, are often cold, swollen, and pale or blue. These are probably secondary effects of immobilization, as pointed out long ago by Lewis and Pickering. Erythema and edema, burning pain, and cold sensations surely can be evoked by peripheral nerve irritation, particularly of C and A-δ fibers as discussed in Chap. 8.

Autonomic Dysfunction Anhidrosis and orthostatic hypotension, two of the most frequent manifestations of autonomic dys-
function, predominate in certain types of polyneuropathy. They occur most frequently in amyloidosis and certain hereditary small-fiber polyneuropathies, especially diabetic, and several congenital types. In addition, they are among the main features of an acute autonomic polyneuropathy called panautonimia (Young, Adams, et al, Low et al) and can be prominent in some cases of GBS. These dysautonomic conditions are described in detail in Chap. 26 and later in this chapter.

Other manifestations of autonomic paralysis are small or medium-sized unreactive pupils that are unusually sensitive to certain drugs (pages 241 and 462); lack of sweat, tears, and saliva; sexual impotence; weak bowel and bladder sphincters with urinary retention or overflow incontinence; and weakness and dilatation of the esophagus and colon. As a result of vagal and other parasympathetic dysfunction, the normal variability of heart rate with respiration (sinus arrhythmia) is lost and there may be paralytic ileus or dyscoordinated peristalsis, as well as achlorhydria and hyponatremia. Some of these abnormalities are found in diabetic and amyloid polyneuropathy. In general these autonomic disturbances correspond to degeneration of unmyelinated fibers in the peripheral nerves.

In any neuropathy involving sensory nerves, there is loss of autonomic function in the same zones as sensory loss. This is not true of radicular diseases because the autonomic fibers join the spinal nerves more distally. Such changes in sweating and cutaneous blood flow may be demonstrated by a number of special tests, as described in Chap. 26.

**Fasciculations, Cramps, and Spasms** (See also Chap. 55) Fasciculations and cramps, while not uncommon, are typically not prominent features in most polyneuropathies and in this respect there is a difference from diseases of the anterior horn cells where they are important features. There are exceptions, however. Chronic root compression can lead to fasciculations or painful spasms in the innervated muscles. Occasionally one observes a state of mild motor polyneuropathy that, upon recovery, leaves the muscles in a state variably referred to as myokymia, continuous muscular activity, and neuromyotonia as discussed in Chaps. 45 and 54. All the affected muscles ripple and quiver and occasionally cramp. Use of the muscles increases this activity, and there is a reduction in their contractile efficiency, which the patient senses as a stiffness and heaviness. In some instances this apparently constitutes the entire neuropathic syndrome and may be relieved by carbamazepine or phenytoin. Other closely related phenomena are spasms or involuntary movements of the toes and feet. The latter, referred to by Spillane and colleagues as the syndrome of painful legs and moving toes, is attributed by Nathan to eptic discharges in sensory roots, ganglia, or nerves, evoking both pain and organized movements. This is one cause of a nocturnal restless leg syndrome, the more common type being idiopathic and not associated with features of peripheral nerve disease. Other possible mechanisms for cramps and spasms are ephaptic cross-transmission, segmental hyperactivity from deafferentation, and neuronal sprouting during reinnervation. In yet other instances, the muscle activity induces odd postures or slow writhing movements that Jankovic and van der Linden have likened to dystonia. The precise pathophysiology of these spontaneous and asynchronous activities of motor neurons is not known. Stimulation of a motor nerve, instead of causing a brief burst of action potentials in the muscle, results in a prolonged or dispersed series of potentials lasting several hundred milliseconds. Evidently, branched axons involved in collateral innervation have an unstable polarization that may last for years.

**APPROACH TO THE PATIENT WITH PERIPHERAL NEUROPATHY**

In this field, the clinician is faced with several problems: (1) establishing the existence of disease of the peripheral nervous system; (2) distinguishing by clinical tests which of the main topographic syndromes it represents; (3) determining if the problem is predominantly of a motor or sensory nature, or is of mixed type and whether the myelin sheath or the axon is the main target of disease; and (4) establishing the temporal course of disease. When taken together, these features greatly limit the diagnostic possibilities and determine the underlying disease and possible treatment.

**Topographic and Clinical Patterns of Neuropathy** (Table 46-1)

At the outset it must be determined whether the neurologic findings correspond to one of the following syndromic patterns:

1. Polynneuropathy
2. Radiculopathy or polyradiculopathy
3. Neuronopathy—motor or sensory
4. Mononeuropathy
5. Multiple mononeuropathies (mononeuropathy, or mononeuritis multiplex)
6. Plexopathy (involvement of multiple nerves in a plexus)

A discussion of these patterns is given in Chap. 9 but the main facts are repeated here:

In **polyneuropathy**, a generalized process affecting the peripheral nerves, weakness is relatively symmetrical from the beginning and progresses bilaterally; reflexes are lost in affected parts, but particularly at the ankles; sensory complaints and loss of sensation are most pronounced distally, and in the feet before the hands in most cases.

**Polyradiculopathy**, a disease of multiple spinal roots, differs from polyneuropathy in that the neurologic signs are asymmetrical, and with an erratic distribution that may, for example, be proximal in one limb and distal in another. Always, weakness and zones of sensory loss can only be explained on the basis of involvement of one or more roots. Pain in the sensory distribution of the roots is a common feature. A single **radiculopathy**, most often the result of root compression by disease of the spinal column, is identified by the presence of pain, sensory, motor, and reflex change solely in the distribution of a spinal nerve root. The distinction from mononeuropathy (see later) is not always apparent, and one must resort to a reference or to memorized knowledge of the motor and sensory innervation patterns of each. (The reader should refer to Figs. 9-1, 9-2, and 9-3.) Most helpful is the limitation of sensory loss to one of the dermatomes but it so happens that there is adequate overlap between adjacent dermatomes that such a pattern is not easily discerned. Some of the specific patterns of weakness that arise from a mononeuropathy as compared to radiculopathy are mentioned later.

In **sensory neuronopathy**, the ganglion cells rather than the peripheral sensory nerves are predominantly affected. This gives rise to symptoms and signs of sensory loss in both a proximal and distal distribution, including the scalp, thorax, abdomen, and but-
tsocks as well as the extremities; sensory ataxia is a common accompaniment. There is no weakness but movements may be awkward as a result of a sensory ataxia. Motor neuronopathy is essentially the opposite condition, a disorder of the anterior horn cells causing weakness, fasciculations, and atrophy in a widespread distribution and, therefore, not properly a process of the peripheral nerves.

Mononeuropathy is the most circumscribed form of peripheral nerve disease. It is reflected by weakness and sensory loss in the territory of a single peripheral nerve. Certain specific features serve to differentiate mononeuropathy from a radiculopathy—for example, weakness in dorsiflexion and evasion of the foot is referable to the peroneal nerve or to the L5 nerve root; however, inversion of the foot, innervated by the tibial nerve, is affected, only with L5 root lesions. The distribution of sensory loss also aids in distinguishing the two processes; for example, in the aforementioned case the region of sensory change corresponding to the L5 root extends almost up to the knee on the anterior surface of the foreleg, whereas it ends a limited distance above the ankle in the case of a peroneal nerve lesion (see the sensory maps on pages 129, 130, and 132). The cumulation of multiple mononeuropathies, termed mononeuritis multiplex, may at times be difficult to differentiate from polynuropathy as discussed further on.

Plexopathies (brachial or lumbosacral) create the most confusing patterns of motor and sensory involvement; only one limb is affected but the motor, sensory, and reflex loss do not conform to a pattern of several adjacent nerve roots or nerves. Knowledge of the innervation of the involved muscles at the level of the plexus usually clarifies the situation.

The apparent complexity of peripheral nerve disease is greatly simplified by recognizing that, of the multitude of diseases, each manifests itself by one or another of above-described topographic and sensory-motor patterns for which reason the pattern of neuropathy sets limits on the etiologic possibilities.

In the analysis of a polyneuropathy it is of further value to determine whether the process is predominantly motor with less sensory involvement (motor-sensory), or the converse (sensori-motor), or purely sensory, motor, or autonomic. The time course of the disease is also extremely informative. An acute onset (i.e., rapid evolution) is nearly always diagnostic of an inflammatory, immunologic, toxic, or vascular etiology. The other extreme, a polyneuropathy evolving slowly over many years, is indicative of a hereditary or, rarely, a metabolic disease. Most of the toxic, nutritional, and systemic diseases of nerve develop subacutely or are of an “early chronic” or subacute nature, appearing over several weeks and months. In addition to the patient’s report of the progress of symptoms, signs such as muscle atrophy signify a process of relatively long-standing, at least several months in duration.

The etiologic diagnosis of polyneuropathy is further aided by attempting to deduce whether the myelin sheath or the axon is primarily involved (i.e., demyelinating or axonal). Sometimes the neurologic examination alone is sufficient to make this distinction, but greater precision is attained from nerve conduction studies and needle examination of muscles [electromyogram (EMG)]. The latter test also helps to detect primary disorders of muscle (myopathies) and separate them from neurogenic denervation or neuromuscular block. The electrical examinations of nerve and muscle described in Chap. 45, therefore, clarify the type of abnormality in each of the main categories of neuropathic disease and greatly reduce the number of possible diagnoses. In a few instances, the EMG abnormalities are so characteristic as to virtually define a neuropathy, e.g., chronic demyelinating motor neuropathy with multifocal conduction block. Other useful laboratory procedures are (1) biochemical tests to identify metabolic, nutritional, or toxic states; (2) CSF examination (increase in protein and in cells that indicate radicular or meningeal involvement); (3) nerve and muscle biopsy; (4) measurement of immunoglobulins and antineural antibodies that relate to immune-mediated neuropathies; (5) genetic testing for several of the inherited neuropathies; and (6) nerve biopsy.

Once having established that the patient has a disease of the peripheral nerves and having ascertained its clinical and electrophysiologic pattern and time course, one is usually able to determine its nature. This is accomplished most readily by allocating the case in question to one of the categories in Table 46-2, wherein the peripheral nerve diseases are classified syndromically according to their mode of evolution and clinical presentation. Again, by categorizing the neuropathic syndrome in this way by topography and time course and by motor or sensory predominance, only a limited number of diagnoses are possible. These are discussed in the sections that follow.

Our use of the terms acute, subacute, and chronic neuropathy must be explained. By acute we mean evolution in terms of days and by subacute, weeks. Chronic is divided into two groups: one in which the neuropathy has progressed for a period of several months to a few years, and another in which progression is over several years, most of which prove to have a genetic cause. It can be restated that these temporal properties are, with the topographic pattern, the main determinants in the categorization of neuropathy.

Diseases of the peripheral nerves are considered in a more comprehensive fashion in the two-volume monograph Peripheral Neuropathy, edited by Dyck and colleagues. Also recommended are more concise monographs on this subject by Schaumburg and associates and by Asbury and Thomas and the atlas on the pathology of peripheral nerve by King.

SYNDROME OF ACUTE MOTOR PARALYSIS WITH VARIABLE DISTURBANCE OF SENSORY AND AUTONOMIC FUNCTION

A number of subtle differences separate the polyneuropathies comprising this category: (1) acute inflammatory demyelinating or axonal polyneuropathy (GBS), (2) vasculitic polyneuropathies, (3) porphyria, (4) certain toxic polyneuropathies, and (5) acute sensory and autonomic polyneuropathies. Of these various acute polyneuropathic diseases, the Guillain-Barré demyelinating syndrome, because of its frequency and gravity, is most demanding of the physician’s attention.

Guillain-Barré Syndrome (Landry-Guillain-Barré-Strohl Syndrome, Acute Inflammatory Polyneuropathy, AIDP)

This acute condition, generally referred to as GBS, is the most common cause of acute or subacute generalized paralysis. (It was at one time rivaled by polio in frequency.) It occurs in all parts of the world and in all seasons, affecting children and adults of all ages and both sexes. A mild respiratory or gastrointestinal infection precedes the neuropathic symptoms by 1 to 3 weeks (sometimes longer) in about 60 percent of cases. Typical is a nongravit upper respiratory infection but almost every known febrile infection and

Table 46-2
The principal neuropathic syndromes and their causes

I. Syndrome of acute motor paralysis with variable disturbance of sensory and autonomic function
   A. Guillain-Barre syndrome (GBS; acute inflammatory polyneuropathy; acute autoimmune neuropathy); see also Table 46-3
   B. Acute axonal form of GBS
   C. Acute sensory neuropathy and neuronopathy syndrome
   D. Diphtheritic polyneuropathy
   E. Porphyric polyneuropathy
   F. Certain toxic polyneuropathies (thallium, triorthocresyl phosphate)
   G. Rarely, paraneoplastic
   H. Acute pandysautonomic neuropathy
   I. Tick paralysis
   J. Critical illness polyneuropathy

II. Syndrome of subacute sensorimotor paralysis
   A. Symmetrical polyneuropathies
      1. Deficiency states: alcoholism (beriberi), pellagra, vitamin B12 deficiency, chronic gastrointestinal disease (see Chap. 41)
      2. Poisoning with heavy metals and solvents: arsenic, lead, mercury, thallium, methyl n-butyl ketone, n-hexane, methyl bromide, ethylene oxide, organophosphates (TOCP etc.), acrylamide (see Chap. 43)
      3. Drug toxicity: isoniazid, ethionamide, hydralazine, nitrofurantoin and related nitrofurazones, disulfiram, carbon disulfide, vincristine, cisplatin, paclitaxel, chloramphenicol, phenytoin, pyridoxine, amitriptyline, dapsone, stilbamidine, trichlorethylene, thalidomide, clioquinol, amiodarone, adulterated agents such as L-tryptophan
      4. Uremic polyneuropathy (see Chap. 40)
      5. Subacute inflammatory polyneuropathy
   B. Asymmetrical neuropathies (mononeuropathy multiplex)
      1. Diabetes
      2. Polyarteritis nodosa and other inflammatory angiopathic neuropathies (Churg-Strauss, hypereosinophilic, rheumatoid, lupus, Wegener granulomatosis, isolated peripheral nervous system vasculitis); see also Table 46-3
      3. Mixed cryoglobulinemia
      4. Sjogren-sicca syndrome
      5. Sarcoidosis
      6. Ischemic neuropathy with peripheral vascular disease
      7. Lyme disease
   C. Unusual sensory neuropathies
      1. Wartenberg migrant sensory neuropathy
      2. Sensory perineuritis
   D. Meningeal based nerve root disease (polyradiculopathy)
      1. Neoplastic infiltration
      2. Granulomatous and infectious infiltration: Lyme, sarcoid
      3. Spinal diseases: osteoarthritic spondylitis
      4. Idiopathic polyradiculopathy

III. Syndrome of chronic sensorimotor polyneuropathy
   A. Less chronic acquired forms
      1. Paraneoplastic: carcinoma, lymphoma, myeloma, and other malignancies
      2. Chronic inflammatory demyelinating polyneuropathy (CIDP)
      3. Paraproteinemias
      4. Uremia (occasionally subacute)
      5. Beriberi (usually subacute)
      6. Diabetes
      7. Connective tissue diseases
      8. Amyloidosis
      9. Leprosy
      10. Hypothyroidism
      11. Benign sensory form in the elderly
   B. Syndrome of more chronic polyneuropathy, genetically determined forms (see Table 46-6)
      1. Inherited polyneuropathies of predominantly sensory type
         a. Dominant mutilating sensory neuropathy in adults
         b. Recessive mutilating sensory neuropathy of childhood
         c. Congenital insensitivity to pain
         d. Other inherited sensory neuropathies, including those associated with spinocerebellar degenerations, Riley-Day syndrome, and the universal anesthesia syndrome
Table 46-2 (Continued)

The principal neuropathic syndromes and their causes

C. Inherited polyneuropathies of mixed sensorimotor types
   1. Idiopathic group
      a. Peroneal muscular atrophy [Charcot-Marie-Tooth; CMT types I (demyelinating) and II (axonal) and CMTX]
      b. Hypertrophic polyneuropathy of Dejerine-Sottas, adult and childhood forms (CMT3)
      c. Roussy-Lévy polyneuropathy (CMT3)
      d. Polyneuropathy with optic atrophy, spastic paraplegia, spinocerebellar degeneration, mental retardation, and dementia
      e. Hereditary liability to pressure palsy (HNPP)
   2. Inherited polyneuropathies with a recognized metabolic disorder (see also Chap. 37)
      a. Refsum disease
      b. Metachromatic leukodystrophy
      c. Globoid-body leukodystrophy (Krabbe disease)
      d. Adrenoleukodystrophy
      e. Amyloid polyneuropathy
      f. Porphyric polyneuropathy
      g. Anderson-Fabry disease
      h. Abetalipoproteinemia and Tangier disease

IV. Neuropathy associated with mitochondrial diseases (see Chap. 37)

V. Syndrome of recurrent or relapsing polyneuropathy
   A. Guillain-Barré syndrome
   B. Porphyria
   C. Chronic inflammatory demyelinating polyneuropathy
   D. Certain forms of mononeuritis multiplex
   E. Beriberi or intoxications
   F. Refsum disease, Tangier disease

VI. Syndrome of mononeuropathy or plexopathy
   A. Brachial plexus neuropathies
   B. Brachial mononeuropathies
   C. Causalgia
   D. Lumbosacral plexopathies
   E. Cural mononeuropathies
   F. Migrant sensory neuropathy
   G. Entrapment neuropathies

Immunization has at one time or another been reported to precede GBS (some perhaps coincidentally). In recent years, it has come to be appreciated from serologic studies that the enteric organism *Campylobacter jejuni* is the most frequent identifiable antecedent infection but it accounts for only a relatively small proportion of cases. Other antecedent events or associated illnesses include viral exanthems and other viral illnesses [cytomegalovirus (CMV), Epstein-Barr virus (EBV), HIV], bacterial infections other than *Campylobacter* (*Mycoplasma pneumoniae*, Lyme disease), exposure to thrombolytic agents, and lymphoma (particularly Hodgkin disease). The administration of outmoded antirabies vaccines and the A/New Jersey (swine) influenza vaccine, given in late 1976, was associated with a slight increase in the incidence of GBS and at least one subsequent influenza vaccination program has been associated with a marginal increase in cases. Trauma and surgical operations may precede the neuropathy, but a causal association to them remains uncertain.

**Historical Background** The earliest description of an afebrile generalized paralysis is probably that of Wardrop and Ollivier, in 1834. Other important landmarks are Landry’s report (1859) of an acute, ascending, predominantly motor paralysis with respiratory failure, leading to death; Osler’s (1892) description of “febrile polyneuritis”; the account by Guillain, Barré, and Strohl (1916) of a benign polyneuritis with albuminocytologic dissociation in the CSF (increase in protein without cells); and the elaboration of the clinical picture by many British and American physicians. The first comprehensive account of the pathology of GBS was that of Haymaker and Kernohan (1949), who stressed that edema of the nerve roots was an important change in the early stages of the disease. Subsequently, Asbury, Arnason, and Adams (1969) established that the essential lesion, from the beginning of the disease, is a perivascular mononuclear inflammatory infiltration of the roots and nerves. More recently it has been found that complement deposition on the myelin surface may be the earliest immunologic event. For details of the historical and other aspects of this disease, see the monographs by Ropper and colleagues and by Hughes.

**Incidence** The reported incidence rate has varied from 0.4 to 1.7 cases per 100,000 persons per year; the latter figure is probably the more accurate. It is generally nonseasonal and nonepidemic but isolated seasonal outbreaks have been recorded in rural China following exposure of children to *C. jejuni* through chicken feces deposited in rice paddies. Year after year, between 15 and 25 patients are admitted to each of our institutions. Females are slightly more susceptible. The age range of our consecutive patients has been 8 months to 81 years, with attack rates highest in persons 50 to 74 years of age. Cases are known in infants and in the very aged.
Symptomatology  The typical case of GBS is readily identified. Paresthesias and slight numbness in the toes and fingers are the earliest symptoms; only infrequently are they absent throughout the illness. The major clinical manifestation is weakness that evolves more or less symmetrically over a period of several days to a week or two, or somewhat longer. The proximal as well as distal muscles of the limbs are involved, usually the lower extremities before the upper (thus the older term Landry’s ascending paralysis); the trunk, intercostal, neck, and cranial muscles may be affected later. The weakness progresses in about 5 percent of patients to total motor paralysis with respiratory failure within a few days. In severe cases the ocular motor nerves are paralyzed and even the pupils may be unreactive.

More than half of the patients complain of pain and an aching discomfort in the muscles, mainly those of the hips, thighs, and back; these symptoms are frequently mistaken for lumbar disc disease, back strain, and various orthopedic diseases. A few describe burning in the fingers and toes and if this appears as an early symptom, it may become a persistent management problem. Sensory loss occurs to a variable degree during the first days and may be barely detectable. By the end of a week, vibration and joint position sense in the toes and fingers are usually reduced; when such loss is present, deep sensibility (touch-pressure-vibration) tends to be more affected than superficial (pain-temperature).

Reduced and then absent tendon reflexes are consistent findings. Rarely, only the ankle reflexes are lost during the first week of illness. At an early stage, the arm muscles may be less weak than the leg muscles, and in a few cases, they are spared almost entirely. Facial diplegia occurs in more than half of cases, sometimes bilaterally at the same time, or sequentially over days. Other cranial nerve palsies, if they occur, usually come later, after the arms and face are affected; infrequently they are the initial signs in a variant pattern of disease as described below.

Disturbances of autonomic function (sinus tachycardia and less often bradycardia, facial flushing, fluctuating hypertension and hypotension, loss of sweating, or episodic profuse diaphoresis) are common in minor form, and only infrequently do these abnormalities become pronounced or persist for more than a week. Urinary retention occurs in about 15 percent of patients soon after the onset of weakness, but catheterization is seldom required for more than a few days. There are in addition numerous medical complications that may arise, are related to a preceding viral infection.

ophthalmopлегic form also exists; it may be coupled with the pharyngeal-cervical-brachial pattern mentioned earlier. The ophthalmoplegia, whether occurring alone or with weakness or ataxia of other parts, is almost uniformly associated with a specific antineuronal antibody, anti-GQ_1b. The ophthalmoplegic pattern raises the possibility of myasthenia gravis, botulism, diphtheria, tick paralysis, and basilar artery occlusion. Bilateral but asymmetrical facial and abducens weakness, coupled with distal paresthesias or with proximal leg weakness, are other fairly common variants in our experience (Ropper, 1994). The tendon reflexes may be absent initially only at the ankles or at the knees. Lyme disease and sarcoidosis are then considerations in diagnosis.

Paraparetic, ataxic, and purely motor or purely sensory forms of the illness have also been observed. Less difficulty attends these diagnoses if paresthesias in the acral extremities, progressive reduction or loss of reflexes, and relative symmetry of weakness appear after several days of signs. The laboratory tests that affirm the diagnosis of typical GBS give similar but generally milder abnormalities if they are carefully sought in all these variant forms.

There has been a recent tendency to separate a group of cases with presumed diffuse axonal damage on the basis of an abrupt and explosive onset, severe paralysis, minor sensory features, and the electrophysiologic finding of inexcitability of nerves. This axonal type of GBS represents 5 percent (or fewer) of cases but its identification has some value in that a poor response to treatment and very protracted recovery are to be expected in most cases. This variant is described later.

In a few patients the weakness continues to evolve for 3 to 4 weeks or even longer. From this group a chronic form of demyelinating neuropathy (chronic inflammatory demyelinating polyneuropathy, or CIDP) often emerges and an intermediate group that progresses for 4 to 8 weeks and then improves can be identified (see further on).

Acute Axonal Form of Guillain-Barré Syndrome  This subject has been alluded to earlier. Feasby and colleagues drew attention to an acute axelofic polyneuropathy clinically similar to GBS but characterized pathologically by widespread and severe axonal degeneration. In their initial report they described five patients, all with a rapid evolution of polyneuropathy and very slow and poor recovery. Unlike the common form of GBS, muscle atrophy in these patients became apparent relatively early in the disease (within weeks). The defining EMG features were the presence of
numerosely inexcitable motor nerves and signs of extensive denervation. Others, however, have questioned the specificity of this finding since the inability to excite motor nerves may also signify a distal demyelinating block, from which complete recovery is possible (Triggs et al). Nevertheless, most cases of very abrupt and severe denervating paralysis, particularly if postinfectious, are due to this form of GBS (Ropper 1986).

Postmortem examinations in these cases have disclosed severe axonal degeneration in nerves and roots, with minimal inflammatory changes and little demyelination, even early in the disease. Based on prominent deposits of complement and the presence of macrophages in the periaxonal space, a humoral antibody directed against some component of the axolemma has been postulated by Griffin and associates. Visser and colleagues reported similar findings in a series of acute motor polyneuropathies from Holland. The outbreaks of motor neuropathy that occur seasonally in rural China have many of the same characteristics. These cases appear to be triggered largely by C. jejuni infections. Some but not all sporadic instances of acute axonal GBS have been preceded by the same infection. It is noteworthy, however, that infection with the same bacteria can induce a typical demyelinating form of GBS. A proportion of cases, perhaps one quarter, are associated with circulating antibodies to the GM1 ganglioside of peripheral nerve, and some of these in turn reflect recently preceding infection with C. jejuni. The acronyms AMAN (acute motor) and AMSAN (acute motor-sensory axonal neuropathy) are equivalents to axonal GBS.

Another variant of this illness of which we have seen several instances has been an acute multifocal neuropathy with electrophysiologic motor conduction block that leaves the reflexes unaltered and is related to anti-GM antibody (Capasso et al). A chronic form of this illness, termed multifocal motor neuropathy, is more common and better understood (see further on).

Most experience with the generalized axonal form of GBS indicates that recovery is prolonged and complete resolution of weakness is uncommon. Intravenous administration of immune globulin (IVIG) and plasma exchange, the usual treatments for GBS as discussed later, have had slight beneficial effect but their use is not associated with the degree of improvement seen in demyelinating cases.

Whether this acute axonal polyneuropathy is a distinct entity or a variant of GBS cannot be answered with certainty. This may prove to be a semantic issue, depending on one’s definition of the clinical, immunologic, and pathologic boundaries of GBS. Certainly, there is a degree of axonal damage in all severe cases of GBS, even when the predominant process is demyelinating. Currently we prefer to distinguish these cases from typical GBS if only to lower expectations for the response to immune treatments and for the ultimate clinical recovery. It should be reemphasized that the presence of electrically inexcitable nerves alone may be due to conduction block and give a misleading impression of axonal damage; the prognosis for cases with conduction block may be quite good. The differential diagnosis includes critical illness polyneuropathy and the rarer entities of porphyric neuropathy and tick paralysis.

**Laboratory Findings** The most important laboratory aids are the electrodiagnostic studies and the CSF examination. The CSF is under normal pressure and is acellular or contains only a few lymphocytes in all but 10 percent of patients; in the latter group, 10 to 50 cells (rarely more) per cubic millimeter, predominantly lymphocytes, may be found. The number of cells then decreases rapidly in a matter of 2 to 3 days; persistent pleocytosis suggests an alternate or additional diagnosis such as neoplastic meningitis, HIV, or Lyme infection. We have been unable to relate pleocytosis in the spinal fluid with any of the clinical features of GBS or to the severity of illness. Usually, the protein content is normal during the first few days of symptoms, but then it begins to rise, reaching a peak in 4 to 6 weeks and persisting at a variably elevated level for many weeks. The increase in CSF protein is probably a reflection of the widespread inflammatory disease of the nerve roots, but high values have had no clinical or prognostic significance in our material, perhaps apart from a few exceptional cases of pseudotumor cerebri (Ropper and Marmarou). In a few patients (fewer than 10 percent) the CSF protein values remain normal throughout the illness. It is worth stating that from our experience, among patients with Fisher syndrome and other restricted or axonal forms of GBS, there is a higher proportion with normal or only slightly elevated protein values.

Abnormalities of nerve conduction are early and dependable diagnostic indicators of GBS. In cases with a typical clinical and EMG presentation one can probably dispense with the CSF analysis as a confirmatory test. The most frequent early electrodiagnostic findings are a reduction in the amplitude of muscle action potentials, slowed conduction velocity, and conduction block in motor nerves singly or in combination (see Chap. 45). Prolonged distal latencies (reflecting distal conduction block) and prolonged or absent F-responses (indicating involvement of proximal parts of nerves and roots) are other important diagnostic findings, all reflecting focal demyelination. The H-reflex is almost always very delayed, or more often absent, but this does little more than confirm the loss of ankle reflexes. Although a limited electrodiagnostic examination may be normal early in the illness, a more thorough study, which includes measurement of late responses, almost invariably shows disordered conduction in an affected limb within days of the first symptom. Early on, features that indicate widespread axonal damage (the “axonal GBS” discussed earlier) portend a poor and protracted recovery in both young and old patients.

The clinical, CSF, and electrodiagnostic criteria for GBS have been reassessed by Asbury and Cornblath and are discussed in detail in the monograph by Ropper et al.

Most patients with acute GBS have shown gadolinium enhancement of the cauda equina roots on magnetic resonance imaging (MRI; 21 of 24 patients in our study), and this may serve as a useful test in complicated cases (Gorson, Ropper, et al).

Abnormalities of liver function occur in fewer than 10 percent of patients, probably reflecting a recent or ongoing viral hepatitis, usually due to CMV or EBV infections (rarely one of the hepatitis viruses). T-wave and other electrocardiographic changes of minor degree are reported frequently but are evanescent. The sedimentation rate is normal unless there is an additional process of infectious, neoplastic, or autoimmune nature, any of which can occasionally coexist with GBS. Hyponatremia occurs in a proportion of cases after the first week, especially in ventilated patients. This is usually attributable to the syndrome of inappropriate antidiuretic hormone secretion (SIADH), but a natriuretic type also occurs, from an excess of atrial natriuretic factor. Transient diabetes insipidus is a rare and unexplained complication. We are unable to comment on a high rate of proteinuria and glomerulonephritis reported by several groups in cases of GBS, but have found it only infrequently.

**Pathologic Findings** These have had a relatively consistent pattern and form. Even when the disease is fatal within a few days,
Figure 46-3. Diagram of probable cellular events in acute inflammatory polyneuropathy (Guillain-Barré syndrome). A. Lymphocytes attach to the walls of endoneurial vessels and migrate through the vessel wall, enlarging and transforming as they do so. At this stage no nerve damage has occurred. B. More lymphocytes have migrated into the surrounding tissue. The first effect on the nerve is breakdown of myelin, the axon being spared (segmental demyelination). This change appears to be mediated by the mononuclear exudate, but the mechanism is uncertain. C. The lesion is more intense, polymorphonuclear leukocytes being present as well as lymphocytes. There is interruption of theaxon in addition to myelin sheath damage; as a result, the muscle undergoes denervation atrophy and the nerve cell body shows central chromatolysis. If the axonal damage is distal, the nerve cell body will survive, and regeneration and clinical recovery is likely. If, as in D, axonal interruption has occurred proximally because of a particularly intense root or proximal nerve lesion, the nerve cell body may die and undergo dissolution. In this situation, there is no regeneration, only the possibility of collateral reinnervation of muscle from surviving motor fibers. (From Asbury et al, 1969, by permission.)

virtually all cases show perivascular (mainly perivenous) lymphocytic infiltrates. Later, the characteristic inflammatory cell infiltrates and perivenous demyelination are combined with segmental demyelination and a variable degree of wallerian degeneration. The cellular infiltrates are scattered throughout the cranial nerves, spinal roots and dorsal roots, and dorsal root ganglia and along the entire length of the peripheral nerves. Sparse focal infiltrates of inflammatory cells (lymphocytes and other mononuclear cells) may also be found in lymph nodes, liver, spleen, heart, and other organs. Swelling of nerve roots at the site of their dural exit has been emphasized by some authors and theorized to cause root damage.

Variations of this pattern of peripheral nerve damage have been observed, each perhaps representing a different immunopathology. Rarely, in a clinically typical case, there may be widespread demyelinative changes and only a paucity of perivascular lymphocytes. In patients whose electrophysiologic tests display severe axonal damage early in the illness as discussed later, the pathologic findings corroborate the predominantly axonal nature of the disease with secondary myelin damage and little inflammatory response. An occasional case has shown an inflammatory process with primary axonal damage rather than demyelination (Honovar et al).

Pathogenesis and Etiology Most of the evidence supports a cell-mediated immunologic reaction directed at peripheral nerve. Waksman and Adams demonstrated that experimentally induced peripheral nerve disease (experimental allergic neuritis, or EAN), clinically and pathologically indistinguishable from GBS, develops in animals 2 weeks after immunization with peripheral nerve homogenates. Brostoff and colleagues suggested that the antigen in this reaction is a basic protein, designated P2, found only in peripheral nerve myelin. Subsequent investigations by these authors indicated that the neuritogenic factor might be a specific peptide in the P2 protein. However, it has become evident that there is no dominant antigen-antibody reaction in GBS and that any number of myelin and axonal elements may be involved in inciting the immune reaction. The pathologic steps in this proposed reaction are diagrammatically illustrated in Fig. 46-3. Hartung and colleagues have found high levels of soluble interleukin (IL)-2 receptors, that is shed from activated T cells, and IL-2 itself in the serum of patients with acute GBS, reflecting activation of these cells. As noted below, complement also seems to be a necessary factor in the initial attack on myelin.

Although the transmission of EAN by T cells sensitized to myelin is strong evidence of their role in GBS, antmyelin antibodies are probably involved in the initial part in the disease. The serum from patients with GBS causes damage to myelin in tissue cultures and induces a characteristic (“vesicular”) form of myelin destruction. Subepineural injection of serum from GBS patients into the sciatic nerve of rats leads to local demyelination and electrical conduction block. The studies by Koski and associates of complement-dependent myelin damage by IgM antimyelin antibodies in GBS provided evidence that antimyelin antibodies are able to initiate myelin destruction even though T cells and that macrophages are the ultimate
effectors of the damage. Indeed, the very earliest change that could be detected by Hafer-Macko and colleagues was the deposition of complement on the inner layer of myelin.

A number of autoantibodies directed at components of nerve ganglioside are detected inconsistently in patients with GBS, the most important being anti-GQ_{b}, which is found in almost all patients with ophthalmoplegia. Approximately one-third of patients have anti-GM_{1} antibodies early in their course, corresponding in most instances to a predominantly motor presentation and to axonal damage, the highest titers usually being associated with cases that follow Campylobacter infections. Antibodies directed against GD_{3,a} or GT_{b} have been associated in some cases with the pharyngeal-brachial-cervical variant. It would therefore seem that casting GBS exclusively as a humoral or as a cellular immune process is an oversimplification.

An unanswered question is how the immune reaction is initiated in humans. All attempts to isolate a virus or microbial agent from nerves or to demonstrate one by electron microscopy have failed, and it is more likely that a variety of agents—viral, bacterial (particularly C. jejuni), certain vaccines, and perhaps neural injury itself—are all capable, in susceptible individuals, of precipitating an immune response against components of autologous peripheral myelin. The occurrence of GBS in patients with acquired immune deficiency syndrome (AIDS) or with EBV or CMV infections simply indicates that these agents, too, induce such an autoimmune response without implicating a direct viral infection of nerve. The observation that only one of many individuals who are infected with a particular pathogen go on to develop GBS suggests that host factors are significant (there is, however, little consistency among HLA types in GBS patients). Whether the aforementioned antibodies against various gangliosides of peripheral nerve are pathogenically active is also uncertain.

Several animal diseases—namely coonhound paralysis of dogs, Marek’s disease of chickens (a viral neuritis), and cauda equina neuritis of horses—all resemble GBS superficially but do not share its main clinical or pathologic features.

**Differential Diagnosis** GBS is not only the most frequent type of acute generalized polyneuropathy seen in a general hospital but also the most rapidly evolving and potentially fatal form. Any polyneuropathy that brings the patient to the brink of death or to respiratory failure within a few days will usually be of this variety. However, several other neurologic conditions must be considered. The immediate problem is to differentiate GBS from acute spinal cord disease marked by sensorimotor paralysis below a defined level and a marked sphincteric disturbance. There may be particular difficulty in the case of an acute lesion of the cord in which tendon reflexes are initially lost (spinal shock), or with necrotizing myelopathy, where a permanent loss of tendon reflexes follows extensive destruction of spinal gray matter (pages 781 and 1064). Also confusing is early and transient urinary retention in a proportion of patients with GBS. Several rules of thumb are useful in distinguishing the disease from a cervical myelopathy: in GBS, the facial and respiratory muscles are usually involved if there is generalized paralysis; the fingertips should be paresthetic once sensory symptoms have ascended to the level of the midcalfes; marked sensory loss proximal to the hands or feet or only of the trunk is unusual early in the illness; and tendon reflexes are almost invariably lost in limbs that are too weak to resist gravity.

A predominantly motor paralysis is the major characteristic of GBS, for which reason the differential diagnosis also includes poliomyelitis, now also caused by the West Nile virus and by enteroviruses other than the polio agent. In all these infectious cases the illness is marked by fever, meningoencephalitic symptoms, early pleocytosis in the spinal fluid, and purely motor and usually asymmetrical areflexic paralysis.

We have seen several times misled by cases of carcinomatous meningitis that caused a subacute and fairly symmetric but mainly distal weakness and appeared similar to GBS. An irregular distribution of weakness between proximal and distal parts, the absence of facial weakness and the appearance of symptoms in one limb after another are always suggestive of this type of neoplastic infiltration of nerve roots. Sciatica may occur with either process but radicular pain in the arms is unusual in GBS. Examination of the spinal fluid usually settles the matter.

Another distinctive problem arises in distinguishing generalized GBS with ophthalmoplegia or the Fisher variant from basilar artery thrombosis. The presence of reactive pupils, areflexia, and F-wave abnormalities in GBS, and of lively reflexes and Babinski signs in the case of brainstem infarction, dependably separates the disorders. Ptosis and oculomotor weakness, features of GBS in some severe generalized cases and in Fisher syndrome, may cause confusion with acute myasthenia gravis, but in the latter disease there are no sensory symptoms and the tendon reflexes are unimpaired. The mandibular muscles remain relatively strong in GBS, whereas the exercised jaw hangs open in myasthenia. Botulism may also simulate GBS, but pupillary reflexes are lost early in botulism (pupillary paralysis occurs mainly in advanced cases of GBS), and there is usually a bradycardia, which is unusual for GBS. Tick paralysis, a disease of children in the United States but affecting both children and adults in Australia, may be nearly impossible to distinguish from GBS unless one finds the tick (page 1034). In addition to an ascending paralysis, both also sometimes cause ataxia and may paralyze eye movements, but sensory loss is not usually a feature of tick paralysis and the CSF protein remains normal. Ingestion of shellfish or reef fish contaminated with saxitoxin, ciguatoxin, or tetrodotoxin (ciguatera, neurotoxic shellfish poisoning) is another cause of acute facial-brachial paresthesias, weakness, tachypnea, and iridoplegia lasting a few days—symptoms that resemble the cranial nerve variants of GBS.

A number of neuromuscular disorders in critically ill patients with systemic medical conditions may be difficult to distinguish from GBS. These include a polyneuropathy of critical illness (see further on); an accelerated neuropathy of renal failure that is seen mainly in diabetic patients receiving peritoneal dialysis (both discussed further on); acute hypophosphatemia induced by hyperalimentation; polymyopathy produced by the administration of high-dose corticosteroids (page 1237); and the prolonged effects of neuromuscular blocking drugs, resulting in the accumulation of their metabolites in patients under conditions of renal failure and acidosis. Episodes of painful paralytic porphyria bear a superficial resemblance to GBS.

**Treatment**

**General medical aspects** In severe cases, respiratory assistance and careful nursing are paramount, since the disease remits naturally and the outlook for recovery is favorable in the majority. About one quarter of our patients in the recent era of treatment have required mechanical ventilation. Since a patient’s condition may deteriorate unpredictably and rapidly in the first days of illness, virtually all but the mildest cases should be admitted to the...
Measurement of maximal inspiratory force and expiratory vital capacity suffices for the bedside estimation of the adequacy of diaphragmatic strength and respiratory function. The trend of these measurements are a guide to the likelihood of respiratory failure. As in poliomyelitis, the strength of the neck muscles and trapezius, which share the same segmental innervation as the diaphragm, tends to parallel diaphragmatic strength. A rough estimate of breathing capacity may be obtained by having the patient count quickly on one deep breath. The ability to reach 20 generally corresponds to a vital capacity of greater than 1.5 L. If a downward trend in these measurements is recognized and the vital capacity diminishes to below about 10 mL/kg, endotracheal intubation and mechanical ventilation are considered. It should be noted that a fairly severe degree of impaired ventilation may occur before the first sign of dyspnea appears and even before there is any elevation of arterial carbon dioxide content. Incipient respiratory failure generally coincides with tachypnea and a slight decrease in arterial oxygen tension (PO2 less than 85 mmHg) reflecting pulmonary atelectasis. If respiratory failure arises gradually, over days or longer, there is slight tachycardia, diaphoresis, restlessness, and tachypnea. Attempts to forestall the use of a positive-pressure ventilator by negative-pressure cuirass-type devices have been unsatisfactory in our experience. Patients with oropharyngeal weakness require intubation even earlier in order to prevent aspiration, but mechanical ventilation is not always necessary at the same time. These treatments are so demanding that the patient should be admitted to an intensive care unit staffed by personnel skilled in maintaining ventilation and airway patency.

The other major aspects of the treatment in severely affected patients involve the management of cardiovascular autonomic instability and the prevention of the many general medical problems that attend any immobilizing critical illness. Hypotension from dysautonomia, which occurs in about 10 percent of severely affected patients, is treated by intravenous volume infusion and by the use of vasopressor agents for brief periods. Extremes of hypertension are managed by short-acting and titratable antihypertensive medications, such as intravenous labetalol. The choice and dosing of an antihypertensive drug is important, since these episodes may be rapidly succeeded by precipitous declines in pressure. It is not clear if severe autonomic changes can be anticipated but various provocative maneuvers such as ocular pressure to elicit heart block are used in some units; we generally omit them.

Prevention of electrolyte imbalance, gastrointestinal hemorrhage, and particularly pulmonary embolism in patients who are bedbound (by the use of subcutaneous heparin or pneumatic compression boots), all require careful attention. Adynamic ileus is a problem in some cases, manifest first by abdominal pain coincident with nasogastric tube feeding and by bloating; it may lead to bowel perforation even if feeding is discontinued. As mentioned, a number of patients become hypotensive, usually from SIADH but occasionally from a natriuresis, and the drop in sodium may be produced or exaggerated by positive-pressure mechanical ventilation. The distinction between the two conditions that cause hypotension determines the course of treatment: fluid restriction in the case of SIADH or salt replacement in the case of sodium loss.

Many patients have bizarre waking dreams or hallucinations after weeks of immobilization. A mode of communication should be worked out by the nursing staff, preferably before the patient is intubated.

Failure to effectively clear the tracheobronchial airways and the need for prolonged mechanical ventilation are the usual indications for tracheostomy. In most cases this procedure can be postponed until the end of the third week of intubation. However, patients who become rapidly quadriplegic and ventilator-dependent may require tracheostomy earlier. Once tracheostomy is performed, careful tracheal toilet and treatment of pulmonary and urinary tract infections by the use of appropriate antibiotics are required. Prophylactic antibiotic treatment is not recommended. With tracheostomy and intensive care, the mortality from the disease can be reduced to about 3 percent (Ropper and Kehne) (see further on under “Prognosis”),

The decisions to wean and then discontinue respiratory aid and to remove the endotracheal or tracheostomy tube are based on the degree and timing of recovery of respiratory function. The weaning process generally begins when the vital capacity reaches approximately 10 mL/kg and comfortable breathing can be sustained for a few minutes. The relative merits of the numerous methods of delivering positive pressure volume-cycled ventilation and its gradual withdrawal are too complex to be covered here but the reader is referred to the monograph, Neurological and Neurosurgical Intensive Care, by Ropper and colleagues.

Physical therapy (passive movement and positioning of limbs to prevent pressure palsies and, later, mild resistance exercises) should begin once they can be comfortably undertaken.

Pharmacological and Immune Globulin Specific treatment of the presumed immune disorder that underlies GBS includes plasma exchange (PE) and intravenous immunoglobulin (IVIG). Our practice has been to closely observe patients who are still able to walk for several days. If the patient has become unable to walk unaided or if he shows a significant reduction in vital capacity or signs of severe oropharyngeal weakness, plasma exchange or IVIG (not both) is instituted promptly. This typically occurs at the fifth to tenth day after the appearance of the first symptoms but may be as early as one day or as late as 3 weeks.

Three large randomized trials comprising more than 500 patients have established the usefulness of plasma exchange administered during the evolving phase of GBS. In patients who are treated within 2 weeks of onset, there is an approximate halving in the period of hospitalization, in the duration of mechanical ventilation, and in the time required to achieve independent ambulation. However, in the largest trial, if the first plasma exchange was delayed for 2 weeks or longer after the onset of the disease, the procedure was of little value. Nonetheless, if a patient continues to progress in the third or fourth week of illness, it is probably still appropriate to institute the exchanges. The most important predictors of responsiveness to plasma exchange treatment are the patient’s age (responders are younger) and the preservation of motor compound muscle action potential amplitudes prior to instituting treatment (McKhan et al). One study has found that the overall condition of patients was better at 6 and 12 months after treatment as compared to untreated patients; other studies have been equivocal on this point.

The advised regimen of plasma exchange removes a total of 200 to 250 mL/kg of plasma in four to six treatments on alternate days, or over a shorter period if there is no coagulopathy. The replacement fluid is saline combined with 5% albumin. The need
for large-bore venous access usually requires the insertion of a
double-lumen subclavian or internal jugular catheters and this may
be the main source of complications (pneumothorax, infection,
hemorrhage). In some patients, treatment can be instituted, and
sometimes the entire course completed, through the antecubital
veins. During and after the procedure, hypotension, hypoprothrom-
bininemia with bleeding (e.g., epistaxis), and cardiac arrhythmias
may occur. Some units prefer to measure the level of fibrinogen,
which is greatly reduced by exchanges before the next exchange
so as a gauge to the risk of potential hemorrhage. Reactions to the
citrate that is used to prevent blood from clotting in the plasma
exchange machine are common but can be obviated by the cautious
addition of calcium to the intravenous return line. Hepatitis and
AIDS are not risks if plasma is replaced with albumin and saline
rather than with pooled plasma.

As effective as plasma exchange is, IVIG (0.4 g/kg per day
for 5 consecutive days) is both easier to administer and probably
safer because there is no need for large intravenous access. The
results of the original trial conducted by van der Meché and col-
leagues have been corroborated in an international study led by
Hughes, in which we participated. The latter study compared
plasma exchange to IVIG and also evaluated their serial use. There
was a tenuous trend toward a better outcome in patients who re-
cieved plasma exchange, and results were perhaps slightly better
in a group who were treated with plasma exchange followed im-
mediately by 5 days of immune globulin infusions; in both in-
stances, however, the differences failed to attain statistical signi-
ficance and the three modes of treatment were said to be equivalent.
Renal failure, proteinuria, and aseptic meningitis manifested most
often by severe headache are rare complications of IVIG. The only
serious reactions we have encountered were in a very few patients
who congenitally lacked IgA and in whom pooled gamma globulin
caused anaphylaxis. We have also encountered a few cases of
marked inflammatory local venous thrombosis in the region of the
infusion site.

After the use of either plasma exchange or IVIG, 5 to 10
percent of patients who initially improve will have a relapse that
becomes apparent several days or up to 3 weeks after completion
of treatment. If there was a good response to the initial therapy, the
same treatment may be repeated or the alternative treatment may
be tried; either can be successful. A few such patients relapse re-
peatedly and have a course indicative of chronic inflammatory de-
myelinating polyneuropathy (see further on). In a few such patients
under our care the disease stabilized after several months in re-
sponse to the administration of corticosteroids, with very gradual
tapering of the dose over several months, or in combination with
repeated courses of IVIG or plasma exchanges.

It should be pointed out that the clinical improvement that
follows the administration of IVIG or PE usually cannot be readily
discerned in an individual patient, i.e., it is apparent only by com-
paring treated and untreated large groups. For this reason it is not
possible to judge that a patient who fails to improve or who worsens
through the period of treatment has indeed derived no benefit from
therapy. The question nevertheless arises regarding further plasma
exchanges or continued infusion of immune globulin in cases of
continued worsening or lack of improvement. Further complicating
the matter are the limited expectations for early improvement in
cases of axonal GBS. Our advice has been to repeat either of the
two treatments if a patient is clearly declining, particularly if there
is evidence of mainly demyelinating disease on the EMG, and if
the illness is not much longer than 3 weeks in duration. Performing
plasma exchanges after the use of IVIG does not make sense to us
(but this notion has not been tested); therefore, we either follow
exchanges with IVIG or, more often, repeat a course of IVIG as
suggested by Farcas and colleagues.

The value of corticosteroids alone in the treatment of GBS has
been disputed for decades. Many clinicians were persuaded of their
benefit. However, two randomized controlled studies, one with
conventional-dose prednisolone and the other with high-dose meth-
ylprednisolone, have failed to demonstrate any beneficial effect
(Hughes et al). Although corticosteroids can no longer be recom-
mended as routine treatment for acute GBS, we have observed a
few instances in which the administration of intravenous high-dose
corticosteroids seemingly halted the progress of the acute disease.

**Prognosis** As already indicated, approximately 3 to 5 percent of
patients do not survive the illness, even in the best-equipped hos-
pitals. In the early stages, death is most often due to cardiac arrest,
perhaps related to dysautonomia, adult respiratory distress syn-
drome, pneumo- or hemothorax, or some type of accidental ma-
chine failure. Later in the illness, pulmonary embolism and other
medical complications (usually bacterial) of prolonged immobi-
лизation and respiratory failure are the main causes.

The majority of patients recover nearly completely (with mild
motor deficits or sensory complaints in the feet or legs). In about
10 percent, however, the residual disability is pronounced; this oc-
curs in those with the most severe and rapidly evolving form of the
disease, when there has been evidence of widespread axonal dam-
age (see later), and in those requiring early and prolonged me-
chanical ventilatory assistance. A consistent predictor of residual
weakness is the EMG finding of severely reduced amplitudes of
muscle action potentials and widespread denervation, both indic-
ative of axonal damage. In patients with respiratory failure, the
average period of machine-assisted respiration has been 22 days
and the period of hospitalization approximately 50 days (these were
twice as long prior to the introduction of PE and IVIG). As a rule,
older adults recover more slowly than younger ones and children
and have more residual weakness.

The most common residual difficulties are weakness of the
lower leg muscles, numbness of the feet and toes, and mild bifacial
weakness. A few patients are left with a sensory ataxia; when this
occurs, it tends to be severe and quite disabling. Distal neuropathic
pain and persistent autonomic problems occur but are infrequent.
All manner of other late symptoms are attributed with little evi-
dence to the illness and should be addressed on their own merits—
fatigue and asthenia, muscle cramps, dizziness, pain, and breath-
lessness. Depression has not been frequent.

The speed of recovery varies but its pace is steady. Often it
occurs within a few weeks or months; however, if axons have de-
generated, their regeneration may require 6 to 18 months or longer.
In our experience, little improvement can be expected in disabilities
that have lasted 3 or more years.

Some 5 to 10 percent of patients suffer one or more recur-
rences of the acute polyneuropathy as mentioned. An illness that
in the beginning appeared to be an acute inflammatory poly-
radiculoneuropathy may fail to stabilize and continue to progress
steadily, or there may be an incomplete remission followed by a
chronic, fluctuating, slowly progressive neuropathy. These chronic
forms of inflammatory neuropathy are described in a later section
of this chapter.
Critical Illness Polyneuropathy

An acute or subacute symmetrical polyneuropathy is a frequent development in critically ill and septic patients, particularly in those with failure of multiple organs (Zochodne et al). This type of neuropathy causes difficulty in weaning a patient from the ventilator, even as the underlying critical illness comes under control. The neuropathic process, predominantly of motor type, varies in severity from an electrophysiologic abnormality without obvious clinical signs to a pronounced quadriplegia with respiratory failure. Sensory symptoms and signs are variable but tend to be mild. Usually the cranial nerves are spared and there are no overt dysautonomic manifestations. In general, the disease appears after several days or more of profound sepsis (now called systemic inflammatory response syndrome—SIRS) and multiple organ failure and is preceded in most instances by a confusional state or a depressed state of consciousness (“septic encephalopathy”). The EMG findings of a primary axonal process with early denervation and a normal CSF distinguish this entity from the typical demyelinating form of GBS. Autopsy material has usually disclosed no inflammatory changes in the peripheral nerves. As mentioned, differentiating critical illness polyneuropathy from the axonal form of GBS is difficult and depends on the context in which the illness occurs. The toxic effects of drugs and antibiotics and nutritional deficiency must be considered in causation, but rarely can they be established. Perhaps some of the many systemic mediators of sepsis are toxic to the peripheral nervous system; tumor necrosis factor has been proposed as one such endogenous toxin.

This form of polyneuropathy must also be distinguished from a poorly understood acute quadriplegic myopathy that sometimes complicates critical illness (page 1237). High doses of corticosteroids, particularly in combination with neuromuscular blocking agents, have been implicated. The acute myopathy, which affects both distal and proximal muscles, is usually heralded by an elevation in the serum creatine kinase (CK) concentration (at times up to several thousand units) and myopathic potentials in the EMG, and there is a unique degeneration of myofilaments in all the muscles. This illness is described in more detail in Chap. 51.

Acute Uremic Polyneuropathy

In addition to the well-known chronic sensory neuropathy associated with chronic renal failure that is discussed later in the chapter, there is a more rapid (“accelerated”) process that has not been widely appreciated as a cause of acute and subacute weakness. Most patients in our series were diabetics with stable end-stage renal failure who had been treated by peritoneal dialysis for their long-standing kidney disease (Ropper, 1993). In contrast to the better characterized and less severe chronic uremic neuropathy (page 1149), generalized weakness and distal paresthesias progress in over one or more weeks until a bedbound state is reached. In some ways the illness simulates GBS. More aggressive dialysis or a change to hemodialysis has little immediate effect, although kidney transplantation is curative. Electrophysiologic studies show some demyelinating features but usually not a conduction block. There is raised CSF protein concentration (not unexpectedly, for there is usually an element of diabetic neuropathy). A few reported cases have been clinically almost indistinguishable from inflammatory demyelinating polyneuropathy, including, in some, a response to plasma exchange or gamma globulin. As with the more common chronic uremic neuropathy, the cause of the acute form is not understood.

Acute Sensory Neuronopathy (Sensory Ganglionopathy)

Attention was drawn to this entity by Sterman and colleagues in a report of three adult patients with rapidly evolving sensory ataxia, areflexia, numbness, and pain, beginning in the face and spreading to involve the entire body. In each instance, the symptoms began within 4 to 12 days following the institution of penicillin therapy for a febrile illness (antibiotics were subsequently shown not to be the cause). Propriocception was profoundly reduced, but there was no weakness or muscle atrophy, despite generalized areflexia. The sensory deficit attained its maximum severity within a week, after which it stabilized and improved very little. Electrophysiologic studies showed absent or slowed sensory conduction but there were no abnormalities of motor nerve conduction or signs of denervation. In two of these patients, the CSF protein content was elevated to 126 and 175 mg/dL. Follow-up observations (for up to 5 years) disclosed no neoplastic or immunologic disorder, the usual causes of such a sensory neuropathy. Lacking pathology, it was assumed, from the permanence of the condition, that sensory neurons were destroyed (sensory neuronopathy). In all likelihood, these cases were postinfectious and immune mediated.

A subsequent series of 42 patients reported by Windebank and colleagues emphasized an asymmetrical and brachial pattern of symptoms in some patients and an initial affection of the face in others. In contrast to Sterman’s cases, the CSF was usually normal and most patients had some improvement or a spontaneous resolution of symptoms. These authors viewed the process as a sensory neuropathy. In this and subsequent reports, as mentioned, antibiotics were not implicated.

At present, this clinical pattern should be viewed as a syndrome rather than as a disease. Probably, some instances are immune-postinfectious in nature. The same pattern of sensory loss evolving in a subacute or chronic manner is well known to occur as a paraneoplastic illness, described further on in this chapter, or in association with the Sjögren syndrome, scleroderma, lupus erythematosus, paraproteinemia, and HTLV-I infection. Certain drugs and other agents, especially cisplatin and excessive intake of pyridoxine, are also causes of a sensory neuronopathy. Also to be distinguished from sensory neuronopathy is a rare form of GBS that involves solely the large sensory fibers and produces ataxia. In the latter, there is usually some degree of proximal weakness, and the sensory changes do not normally extend to the face and trunk.

Diphtheritic Polyneuropathy

(See page 1031)

Some of the neurotoxic effects of Corynebacterium diphtheriae and the mode of action of the exotoxin elaborated by the bacillus are described in Chap. 43. Local action of the exotoxin may paralyze pharyngeal and laryngeal muscles (dysphagia, nasal voice) within 1 or 2 weeks after the onset of the infection and shortly thereafter may cause blurring of vision due to paralysis of accommodation, but these and other cranial nerve symptoms may be overlooked. At this stage, the cranial neuropathy must be distinguished from that of GBS, botulism, and most of all, from myasthenia gravis.

A polyneuropathy, coming 5 to 8 weeks later, takes the form
of an acute or subacute limb weakness with paresthesias and distal loss of vibratory and position sense. The weakness characteristically involves all extremities at the same time or may descend from arms to legs. After a few days to a week or more, the patient may be unable to stand or walk and occasionally the paralysis is so extensive as to impair respiration. The CSF protein is usually elevated (50 to 200 mg/dL). Diphtheritic deaths that occur after the pharyngeal infection has subsided are due to cardiomypathy or, less often, to severe polyneuropathy with respiratory paralysis. This type of polyneuropathy, now quite rare, should be suspected in the midst of an outbreak of diphtheritic infection, as occurred recently in Russia (Logina and Donaghy).

The important pathologic change is one of segmental demyelination without inflammatory reaction of spinal roots, sensory ganglia, and adjacent spinal nerves. Anterior horn cells, axons, peripheral nerves distally, and muscle fibers remain normal (Fisher and Adams).

**Treatment** Diphtheria antitoxin, given within 48 h of the onset of the infection reduces the incidence and severity of neuropathic complications. Antitoxin is probably of little value once the polyneuropathy begins. Thereafter, treatment is purely symptomatic, along the lines indicated for GBS. The prognosis for full recovery is excellent once respiratory paralysis is circumvented.

**Porphyric Polyneuropathy**

A severe, rapidly advancing, more or less symmetrical and mainly motor polyneuropathy—often with abdominal pain, psychosis (delirium or confusion), and convulsions—may be a manifestation of **acute intermittent porphyria**. This type of porphyria is inherited as an autosomal dominant trait and is not associated with cutaneous sensitivity to sunlight. The metabolic defect is in the liver and is marked by increased production and urinary excretion of porphobilinogen and of the porphyrin precursor δ-amino-levulinic acid. The peripheral and central nervous systems may also be affected in another hepatic type of porphyria (the variegate type). In the latter, the skin is markedly sensitive to light and trauma, and porphyrins are at all times found in the stools. Both of these hepatic forms of porphyria are to be distinguished from the rarer erythropoietic (congenital photosensitive) porphyria, in which the nervous system is not affected.

The classic study of acute intermittent porphyria was made by Waldenstrom in 1937. The initial and often the most prominent symptom is moderate to severe colicky abdominal pain. It may be generalized or localized and is unattended by rigidity of the abdominal wall or tenderness. Constipation is frequent and radiographs show intestinal distention (ileus). Attacks last for days to weeks and repeated vomiting may lead to inanition. In latent forms, the patient may be asymptomatic or complain only of slight dyspepsia.

The disease can be identified after some time by its characteristic recurrent attacks, often precipitated by drugs such as sulfonamides, griseofulvin, estrogens, barbiturates, phenytoin, and the succinimide anticonvulsants. The possibility of sensitivity to these drugs must always be kept in mind when convulsions are being treated in the porphyric patient. The first attack rarely occurs before puberty, and the disease is most likely to threaten life during adolescence and early adulthood. In contrast, acute polyneuropathy that appears for the first time in mid- or late adult life is not likely to be porphyric.

The neurologic manifestations are usually those of an acute polyneuropathy involving the motor nerves more severely than the sensory ones; less often both sensory and motor nerves are affected more or less equally and sometimes autonomic nerves as well. The symptoms may begin in the feet and legs and ascend, or they may begin in the hands and arms (sometimes asymmetrically) and spread in a few days to the trunk and legs. Often, the weakness predominates in the proximal muscles of the limbs and limb girdle muscles, in which case there is loss of knee jerks with preservation of reflexes at the ankles. Sensory loss, often extending on to the trunk, is present in half the cases. Facial paralysis, dysphagia, and ocular palsies are features of only the most severe cases. The CSF protein content is normal or slightly elevated.

The course of the polyneuropathy is variable. In mild cases the symptoms regress in a few weeks. Severe cases may progress to a fatal respiratory or cardiac paralysis in a few days, or the symptoms may advance in a saltatory fashion over several weeks, resulting in a severe sensorimotor paralysis that improves only after many months.

A disturbance of cerebral function (confusion, delirium, visual field defects, and convulsions) is likely to precede the severe but not always the mild forms of polyneuropathy, or there may be none of these central features. Cerebral manifestations subside in a few days or weeks, though one of our patients was left with a lasting homonymous hemianopia. Tachycardia and hypertension are frequent in the acute phase of the disease, and fever and leukocytosis may also occur in severe cases. In general, the prognosis for ultimate recovery is excellent, though relapse of the porphyria may result in cumulative involvement of the peripheral nervous system (see discussion of relapsing polyneuropathy further on).

In summary, the most characteristic features are the relapsing nature, acute onset, abdominal pain, psychotic symptoms, predominant motor neuropathy, often, an early biracialial distribution of weakness, truncal sensory loss, and tachycardia. Rarely the neuropathy develops without other symptoms.

The pathologic findings in the peripheral nervous system vary according to the stage of the illness at which death occurs. In the first few days, the myelinated fibers may appear entirely normal, despite an almost complete paralysis. If symptoms had been present for weeks, degeneration of both axons and myelin sheaths are found in most of the peripheral nerves. The relation between the abnormality of porphyrin biosynthesis in the liver and nervous dysfunction has never been explained satisfactorily.

The diagnosis is confirmed by the demonstration of large amounts of porphobilinogen and δ-aminolevulinic acid in the urine. The urine turns dark when standing due to the formation of porphobilinogen and of the porphyrin precursor δ-amino-levulinic acid. The use of intravenous glucose and intravenous he-
phates, and industrial solvents. As a rule, the neuropathies induced by these agents fall into the chronic category (to be discussed further on). Certain drugs, however—notably triorthocresylphosphate (TOCP) and other organophosphates (see page 1037), thallium, and rarely arsenic—produce a polyneuropathy that may be fatal in a matter of days. It should be stressed that organophosphate neuropathy can be identified in almost all instances by the severe anticholinergic effects that are apparent immediately after exposure. Severe and permanent motor paralysis is caused by TOCP; this ultimately proves to be due to involvement of both upper and lower motor neurons.

Thallium salts, when taken in sufficient amount, may produce a clinical picture resembling that of GBS or an acute sensory polyneuropathy. If the salts are taken orally, there is first abdominal pain, vomiting, and diarrhea, followed within a few days by pain and tingling in the toes and fingertips and then rapid weakening of muscles of the limbs, initially the distal ones. As the weakness progresses, the tendon reflexes diminish. Pain sensation is reduced more than tactile, vibratory, and position sense. Persistent acral pain with allodynia has been a major feature in three of the five patients we have examined; in two of our patients there was no weakness, only sensory loss and ataxia. All cranial nerves except the first and eighth may be affected; facial palsy, ophthalmoplegia, nystagmus, optic neuritis with visual impairment, and vocal cord palsy are additional abnormalities, but only in the most severely affected patients. The CSF protein rises to more than 100 mg. Death may occur in the first 10 days, due to cardiac arrest. The early onset of painful paresthesias, sensory loss, and pain localized to joints, back, and chest as well as rapid loss of hair (after a week or two) all serve to differentiate this neuropathy from GBS, porphyria, and other acute polyneuropathies. Relative preservation of reflexes is noteworthy, and rapidly evolving, complete alopecia is a striking feature. Patients with lesser degrees of intoxication may recover completely within weeks or months. Thallium salts act like potassium, and a high intake of potassium chloride hastens the excretion of thallium. Chelating agents are of unproven value but are usually included in treatment.

Some cases of arsenical and possibly mercurial polyneuropathy may also develop acutely. More often these conditions evolve subacutely, for which reason they are discussed further on. As alluded to earlier and in Chap. 43, certain other toxic neuropathies, such as those related to organophosphate or diethylene chloride (Sterno) poisoning, may have an acute onset and progress over days.

In regard to this category of polyneuropathy, it must be pointed out that many instances are imputed with little substantiation to a toxic cause by both patients and unskeptical physicians. Before making such an attribution, it is useful to ask whether the clinical features are compatible with the known neurotoxicity of an environmental agent or drug; whether the severity of symptoms is consistent with degree of presumed exposure (real or imagined); whether the associated systemic signs of an intoxication were present; if other individuals similarly exposed had been affected; and whether symptoms stabilized or improved once the patient had been removed from the presumed source of exposure. Failure to satisfy these precepts generally signifies some other disorder.

Other Acute Polyneuropathies

On occasion, a vasculitic polyneuropathy associated with lupus erythematosus, polyarteritis nodosa, and related disorders may develop as rapidly as GBS, and careful clinical and electrophysiologic testing may be needed to distinguish these disorders. Three of our patients with polyarteritis and one with Churg-Strauss disease became completely paralyzed within a week, and one died of intestinal perforation. However, most cases of neuropathy due to vasculitis evolve more slowly, and the syndrome then assumes an asymmetrical and multifocal distribution, for which reason it is described in the next section. There is no doubt that paraneoplastic neuropathies, discussed further in the subacute category, can evolve more rapidly than is typical for this process and thereby simulate GBS.

We have observed a few patients with alcoholism, occult carcinoma, Hodgkin disease, or renal transplantation who developed an acute polyneuropathy, as rapid in its evolution as GBS, and acute episodes of this type have also been described in patients with Refsum disease.

Acute Autonomic Polyneuropathy (“Pure Pandysautonomia”)

Since the first description of such a case by Young, Adams, and colleagues, a number of others have been recorded as summarized by Low et al. The condition, probably a type of postinfectious polyneuropathy within the category of GBS, is described in detail in Chap. 26. Some success has been achieved by treatment with IVIG.

A subacute and more chronic form, also immune in nature, is described further on under “Idiopathic Autonomic Neuropathy.”

SYNDROME OF SUBACUTE SENSORIMOTOR PARALYSIS

Placed in this category are neuropathies that evolve over several weeks to months and, after reaching their peak of severity, tend to persist for a variable period. Admittedly, the dividing line between such cases and those that evolve over somewhat shorter or longer periods is indistinct; there are diseases of nerve that overlap both the acute and the early chronic categories. In contrast to the acute polyneuropathies, however, most of those that are subacute have prominent sensory features and are of axonal type. The exception is a subacute inflammatory-demyelinative type, essentially a slow form of GBS, evolving over 4 to 8 weeks as described by Hughes and coworkers. Similarly, some instances of diphtheritic neuropathy evolve subacutely. Despite these qualifications, in the end, a symmetrical polyneuropathy syndrome of subacute type most often proves to be due to alcoholism and nutritional deficiency, to a remote effect of cancer (paraneoplastic, as described later), or to poisoning with arsenic, lead, or to the toxic effects of any number of drugs used for therapeutic purposes (cisplatin, nitrofurantoin, iso- niazid, etc.). Occasionally other drugs, metals, and industrial solvents are incriminated; these are discussed in Chap. 43.

Nutritional Deficiency Neuropathy

(See Chap. 41)

In the western world, nutritional polyneuropathy is usually associated with chronic alcoholism. As indicated in page 989, all data point to the identity or at least close relationship between alcoholic neuropathy and neuropathic beriberi. A nutritional factor is responsible for both, though in any given case it often remains unclear whether the deficiency is one of thiamine, nicotinic acid, pyridoxine, pantothenic acid, folic acid, or a combination of these B
vitamins. We have not been persuaded of the existence of a form of polyneuropathy that is attributable solely to the direct toxic effect of alcohol, though claims of such an entity have been made. Nutritional neuropathy and other forms of deficiency neuropathy (Strachan syndrome, pellagra, vitamin B$_{12}$ deficiency, and malabsorption syndromes) are described fully in Chap. 41.

**Paraneoplastic Polyneuropathy and Sensory Ganglionopathy**

(See also page 586)

Although capable of producing diverse clinical presentations, most often the remote effect of cancer takes the form of a predominantly distal, symmetrical sensory, or sensorimotor polyneuropathy occurring as a remote effect of carcinoma or lymphoma. Weakness and atrophy, ataxia, and sensory loss of the limbs may advance over several weeks or months to the point where the patient is confined to a wheelchair or bed; usually the CSF protein concentration is mildly elevated. All these symptoms may occur months or even a year or longer before a malignant tumor is found, although usually the tumor is apparent and is most often lung cancer.

In most series, a mixed sensorimotor polyneuropathy is four to five times more frequent than a purely sensory one. The latter is the more distinctive syndrome (described originally by Denny-Brown); it is characterized by a loss of all modalities of sensation spreading from the distal to the proximal segments of the limbs and eventually to the trunk and face. There is severe ataxia and loss of tendon reflexes, but motor power is retained. More recently, it has been appreciated that the sensory loss in the beginning may have a multifocal distribution. The illness reaches its peak in a few weeks or months, and in a very few instances as mentioned the development has been as rapid as that of GBS. The pathologic changes are those of an inflammatory and destructive sensory neuronopathy (ganglionitis) and are sometimes part of a more widespread disorder of the nervous system related to the anti-Hu antibody (also termed antinuclear neuronal antibody); see page 585. This has proven to be most typical of small-cell cancer of the lung.

In a large series of 71 patients with sensory neuropathy reported by Dalmau and colleagues, more than half were associated with symptomatic inflammatory lesions in the temporal lobes (limbic encephalitis, page 586), the brainstem, and rarely the anterior horn neurons of the spinal cord. Other distinctive paraneoplastic syndromes such as cerebellar degeneration and Lambert-Eaton myasthenic syndrome were combined with polyneuropathy in isolated cases, and there were signs of dysautonomia in 28 percent. Our experience has been otherwise, with most cases of the myasthenic syndrome occurring in isolation.

The CSF protein is moderately elevated but acellular and shows high titers of the anti-Hu antibody. Sensory potentials are usually absent in all nerves after a few weeks but may be spared early on. The localization of anti-Hu antibody to the several affected regions of the nervous system and to the tumor itself has led to speculation that the lung tumors are typically small or inevident because the antibody suppresses tumor growth. Almost all cases of paraneoplastic sensory neuropathy and a proportion of the more nondescript sensory predominant or sensorimotor paraneoplastic polyneuropathies also demonstrate anti-Hu antibodies, making, serum anti-Hu testing useful in distinguishing paraneoplastic varieties of sensory neuropathy and neuronopathy from those due to postinfectious or immune disorders such as Sjögren syndrome and HIV infection. The finding of high antibody titers should lead to detailed radiologic and, in appropriate cases, bronchoscopic or PET examinations to detect an underlying cancer. A rare vasculitic mononeuritis multiplex that occurs with cancer is discussed further on.

An unusual assortment of polyneuropathies have been associated with non-Hodgkin lymphomas of both T- and B-cell types and with several related conditions such as Castleman disease (angiofollicular lymphoid hyperplasia), intravascular T-cell lymphoma (and the related lymphomatoid granulomatosis, page 565), hypersensitivity lymph node hyperplasia (angioimmunoblastic or immunoblastic lymphadenopathy), and Kimura disease (lymphoid hyperplasia with eosinophilia mainly involving skin). In most of these neuropathies, particularly the one associated with Castleman disease, there is a paraproteinemia, often polyclonal, thereby relating this group to the paraproteinemic neuropathies and to osteosclerotic myeloma, discussed later. In several of our cases, the neuropathic manifestations have appeared simultaneously with lymph node enlargement in the groin, axilla, or thorax. Clinically, the illness takes the form of GBS, chronic demyelinating polyneuropathy, subacute motor polyneuropathy or anterior horn cell disease, lumbar and brachial plexopathy, or a polyradiculopathy—each occurring as a paralymphomatous condition clearly separable from cases of meningeal and neural infiltration by tumor. Corticosteroids have been helpful in some of our patients with the lymphoid diseases; in others, the neuropathy resolves spontaneously or with radiation of the lymph nodes but otherwise progresses for months. Vallat and colleagues have summarized their experience with the more conventional types of neuropathy accompanying non-Hodgkin lymphoma. Intravascular lymphoma, a widespread neoplastic and vascular disease described on page 565, may involve the peripheral nerves in a multiple mononeuropathy pattern.

The various forms of paraneoplastic polyneuropathy are manifest clinically in 2 to 5 percent of patients with malignant disease. The figures are higher if one includes the neuropathies accounted for by malnutrition and pressure palsies that occur in the later stages of cancer, and those identified by EMG in asymptomatic patients (Henson and Urich). As alluded to earlier, carcinoma of the lung accounts for about 50 percent of the cases of paraneoplastic sensorimotor polyneuropathy and for 75 percent of those with pure sensory neuropathy (Croft and Wilkinson); nevertheless, these neuropathies may be associated with neoplasms of all types.

Although anti-Hu binds to the peripheral nerve, the pathology of the paraneoplastic polyneuropathies has not been completely defined. In the purely sensory type, there is not only a loss of nerve cells in the dorsal root ganglia but also an inflammatory reaction (Horwich et al)—much the same changes as occur with the sensory neuropathy of Sjögren syndrome. In the mixed sensorimotor polyneuropathy, the degeneration is greater in the distal than it is in the proximal segments of the peripheral nerves, but it extends into the roots in advanced cases. Dorsal root ganglion cells may be reduced in number. If the histologic examination is performed early in the course of the neuropathy, sparse infiltrates of lymphocytes are observed, distributed in foci around blood vessels. Their relation to both segmental demyelination and axonal degeneration of myelinated fibers is unclear. No tumor cells are seen in the nerves or spinal ganglia, unlike the rare instances of carcinomatous and lymphomatous mononeuropathy multiplex, in which tumor cells actually infiltrate nerves. Degeneration of the dorsal columns and chromatolysis of anterior horn cells are secondary to changes in the peripheral nerves and roots.

The overall prognosis of the paraneoplastic neuropathies is poor. Even though the polyneuropathy may stabilize and not pro-
Lead neuropathy is an uncommon disorder. In adults, as a rule, it occurs following chronic exposure to lead paint or fumes (from smelting industries or burning batteries) or from ingestion of liquor distilled in lead pipes. Its most characteristic presentation is a predominantly motor mononeuropathy in the distribution of the radial nerves (wrist and finger drop). In a few personally observed patients, this was the main abnormality but there was also a slight sensory loss in the radial territory of the hand. Less commonly there is foot drop occurring alone or in combination with weakness of the proximal arm and shoulder girdle muscles. As pointed out in Chap. 43, lead neuropathy seldom occurs in children, in whom lead poisoning usually results in a devastating encephalopathy. Although the neuropathy has been known since ancient times, details of the pathology are still obscure. Axonal degeneration with secondary myelin change and swelling and chromatolysis of anterior horn cells has been described. Lead accumulates in the nerve and may be toxic to Schwann cells or to endothelial capillary cells, causing edema. The diagnosis is established by the history of lead exposure, the predominant and restricted motor involvement, the associated medical findings (anemia, basophilic stippling of red blood cell precursors in the bone marrow, a “lead line” along the gingival margins, colicky abdominal pain, and constipation), and the urinary excretion of lead and coproporphyrins. Blood lead levels of more than 70 mg/dL are always abnormal. In patients with lower levels, doubling of the 24-h urinary lead excretion following an infusion of the chelating agent CaNa2 EDTA indicates a significant degree of lead intoxication. Coproporphyrin in the urine is abnormal in any amount, but it may also be found in porphyria, alcoholism, iron deficiency, and other disorders as well as in lead intoxication.

Treatment consists of terminating the exposure to lead and eliminating lead from the bloodstream and the bones as discussed in Chap. 43. For this purpose, penicillamine, which is generally safe and can be administered orally, is preferable to dimercaprol [British antilewisite (BAL)] or EDTA.

Subacute Toxic Neuropathies

Arsenical Polyneuropathy Of the neuropathies caused by metallic poisoning, that due to arsenic is particularly well known. In cases of chronic poisoning, the neuropathic symptoms develop rather slowly, over a period of several weeks or months, and have the same sensory and motor distribution as the nutritional polyneuropathies. Gastrointestinal symptoms, the result of ingestion of arsenic compounds, may precede the polyneuropathy, which is nearly always associated with anemia, jaundice, brownish cutaneous pigmentation, hyperkeratosis of palms and soles, and later with white transverse banding of the nails (Mees lines). The disease is nearly always associated with anemia, jaundice, brownish cutaneous pigmentation, hyperkeratosis of palms and soles, and later with white transverse banding of the nails (Mees lines). The disease is characteristically this form of arsenical neuropathy is generally categorized as the dying-back (axonal degeneration) type. In patients who survive the ingestion of a single massive dose of arsenic, a more rapidly evolving polyneuropathy may appear after a period of 8 to 21 days as discussed earlier. The neuropathy may be preceded by severe gastrointestinal symptoms, renal and hepatic failure, and mental disturbances, convulsions, confusion, and coma—i.e., arsenical encephalopathy—the pathologic basis of which is a brain purpura, or pericapillary hemorrhages. Initially, the neuropathy that develops in this setting may resemble GBS, both clinically and electromyographically (partial conduction block, prolonged F responses).

Diagnosis and treatment of arsenical poisoning are discussed further in Chap. 43.

Lead Neuropathy (Plumbism) Lead neuropathy is an uncommon disorder. In adults, as a rule, it occurs following chronic exposure to lead paint or fumes (from smelting industries or burning batteries) or from ingestion of liquor distilled in lead pipes. Its most characteristic presentation is a predominantly motor mononeuropathy in the distribution of the radial nerves (wrist and finger drop). In a few personally observed patients, this was the main abnormality but there was also a slight sensory loss in the radial territory of the hand. Less commonly there is foot drop occurring alone or in combination with weakness of the proximal arm and shoulder girdle muscles. As pointed out in Chap. 43, lead neuropathy seldom occurs in children, in whom lead poisoning usually results in a devastating encephalopathy. Although the neuropathy has been known since ancient times, details of the pathology are still obscure. Axonal degeneration with secondary myelin change and swelling and chromatolysis of anterior horn cells has been described. Lead accumulates in the nerve and may be toxic to Schwann cells or to endothelial capillary cells, causing edema.
Cytoxic anemia is reversed by the administration of B₁₂, but the neurologic illness is less responsive (page 1092).

Triorthocresyl phosphate and acrylamide are potent peripheral nerve poisons. Both of these drugs cause a dying-back polyneuropathy with axonal degeneration and have been used experimentally to produce this effect. Vacor, a phenylnitrosourea rodenticide, has been taken as a suicidal agent. It gives rise to a profound sensory and autonomic neuropathy with abdominal pain and hyperglycemia due to acute pancreatitis.

Detailed accounts of the clinical and experimental neurotoxicology of these agents can be found in the monograph by Spencer et al.

**Drug-Induced Neuropathies and Neuronopathies** A large number of medications are sources of polyneuropathy of predominantly sensory type. Most are dose-dependent and are therefore more or less predictable after large cumulative doses of the drug have been given (e.g., in chemotherapy) or after prolonged administration for other reasons. Often, in the latter case, the patient and physician fail to connect the sensory symptoms to drug toxicity.

**Antineoplastic Drugs** Among chemotherapeutic agents in current use, cisplatin and carboplatin are known to consistently evoke a predominantly sensory polyneuropathy, which begins several weeks after completion of therapy in at least half of the patients (page 1039). Proprioception and vibratory sensation are most severely impaired. Some patients develop acroodynia and episodic color changes in the fingertips and toes, suggesting that autonomic nerves are also involved; in severe cases there is sensory ataxia and pseudohypotheresis. The severity of histopathologic changes in the peripheral nervous system corresponds to the concentration of platinum in these tissues, the highest concentrations being found in dorsal root ganglia. There may be secondary degeneration in the posterior columns—the basis for a Lhermitte symptom reported by these patients.

The taxanes paclitaxel (Taxol) and the more potent docetaxel (Taxotere), both cited as inhibitors of the depolymerization of neurotubules, are used mainly in the treatment of ovarian cancer. They produce a sensory polyneuropathy similar to that of cisplatin. The nerve lesion regresses slowly with a reduction in dosage (see also page 1040). Pathologic studies have shown a distal axonopathy affecting mainly large fibers.

For decades it has been known that peripheral neuropathy commonly complicates the use of vincristine, an antineoplastic agent widely used in treatment of the lymphomas and leukemia (page 1039). Parasthesias are the most common early symptom, and loss of ankle jerks is an early manifestation. Some degree of weakness usually precedes objective sensory loss; the extensor muscles of the fingers and wrists are affected; later the dorsiflexors of the toes and feet causing foot drop, or, more often in our experience, foot drop may appear first. With the dose regimens currently used, the weakness is usually mild, but in the past some patients became quadriparetic and bedbound. Adults are more severely affected than are children, as are persons with preexisting polyneuropathies. The neuropathy is strictly dose-related, and reduction in dosage is followed by improvement of neuropathic symptoms although this may take several months. Many patients are then able to continue the use of vincristine in low dosage, such as 1 mg every 2 weeks, for many months.

**Antimicrobial Drugs** As mentioned in Chap. 43, isoniazid (INH)-induced polyneuropathy was a common occurrence in the early 1950s when this drug was first used for the treatment of tuberculosis. Symptoms of neuropathy appeared between 3 and 35 weeks after treatment was begun and affected about 10 percent of patients receiving therapeutic doses in the upper range (10 mg/kg daily). The initial symptoms are symmetrical numbness and tingling of the toes and feet, spreading, if the drug is continued, to the knees and occasionally to the hands. Aching and burning pain in these parts then becomes prominent. In addition to sensory loss, examination usually discloses a loss of tendon reflexes and weakness in the distal muscles of the legs. Severe degrees of weakness and loss of deep sensation are observed only rarely.

Isoniazid produces its effects on the peripheral nerves by interfering with pyridoxine metabolism, perhaps by inhibiting the phosphorylation of pyridoxine (the collective name for the B₆ group of vitamins) and decreasing the tissue levels of its active form, pyridoxal phosphate. The administration of 150 to 450 mg of pyridoxine daily, in conjunction with the isoniazid, completely prevents the neuropathy. The same mechanism is probably operative in the neuropathies that occasionally complicate the administration of the isoniazid-related substances such as ethionamide, used sometimes in the treatment of tuberculosis, and the now little-used antihypertensive agent hydralazine. Paradoxically, the taking of extremely high doses of pyridoxine over a prolonged period may, as alluded to earlier, actually cause a disabling, predominantly sensory ganglionopathy (Schaumburg et al).

A relatively mild sensory neuropathy (acral paresthesia) associated with optic neuropathy occasionally complicates chloramphenicol therapy. The chronic administration of metronidazole (used in the treatment of Crohn disease and anaerobic infections) may have the same effect. A predominantly motor neuropathy has been reported with the chronic administration of dapsone, a sulfone used to treat leprosy and certain dermatologic conditions. Stilbamidine, used in the treatment of kala azar, may also induce a purely sensory neuropathy with a propensity to affect the trigeminal nerves.

The introduction in 1952 of nitrofurantoin for the treatment of bladder infections was soon followed by reports of neurotoxicity attributable to the drug. The earliest symptoms are pain and tingling paresthesias of the toes and feet, followed shortly by similar sensations in the fingers. If the drug is not discontinued, the disorder progresses to a severe, symmetrical sensorimotor polyneuropathy. Patients with chronic renal failure and azotemia are particularly prone to neurotoxicity from nitrofurantoin because of diminished drug excretion resulting in high tissue levels. To make matters more complex, the uremic state itself may be responsible for a similar polyneuropathy, so that the distinction between uremic and nitrofurantoin neuropathy in the presence of chronic renal failure may be impossible. The neuropathologic studies of Lhermitte and colleagues disclosed an axonal degeneration in peripheral nerves and sensory roots.

**Cardiac Drugs** Amiodarone, a drug that is commonly used for treating recalcitrant ventricular tachyarrhythmias, induces a motor-sensory polyneuropathy in about 5 percent of patients after several months of treatment. Perhexiline maleate, another drug for the treatment of angina pectoris, may also cause a generalized, predominantly sensory polyneuropathy in a small proportion of patients. Affected persons show a striking neuronal lipidosis. Patients taking niacin to lower blood cholesterol levels may experience intense distal and truncal paresthesias, but no neuropathy has been identified.

**Disulfiram (Antabuse)** The development of a sensorimotor neuropathy similar to that produced by INH is sometimes associated
with the chronic use of disulfiram in the treatment of alcoholism. Its neurotoxic effects have been attributed to the action of carbon disulfide, which is produced during the metabolism of the drug, and is known to cause polyneuropathy and sometimes an optic neuropathy in workers in the viscose rayon industry. Pathologic data, though scant, tend to discredit this notion, insofar as disulfiram evokes a wallerian type of axonal degeneration, whereas carbon disulfide neuropathy is characterized by swollen (giant) axons that are filled with neurofilaments (Bouldin et al).

**Other Pharmaceutical Agents Causing Polyneuropathy** Some patients who have taken phenytoin for decades may show an absence of ankle and patellar reflexes, a mild distal symmetrical impairment of sensation, reduced conduction velocity in the peripheral nerves of the legs, and, rarely, weakness of the distal musculature. The mechanism and frequency of this complication are not clear. The cholesterol lowering "statin" drugs have been implicated in a painful, paresthetic distal axonal polyneuropathy, often, it has been stated, with retained reflexes (Geist et al). More often the problem with statins is one of a toxic myopathy. The frequency of polyneuropathy is very low but, if no other explanation is identified, it may be advisable to discontinue the drug. Colchicine has long been known to cause a myopathy, but a few cases of predominantly axonal sensory neuropathy have also been reported. Thalidomide, which can produce sensory polyneuropathy, had been withdrawn from the market but is now being used again experimentally for graft-versus-host disease and for drug-resistant erythema nodosum, leprous eruptions, and aphtous stomatitis, particularly in AIDS patients—also as an experimental antineoplastic agent for vascular tumors. Thalidomide polyneuropathy is dose-dependent and can be anticipated at certain levels of administration. Severe botulinum poisoning and the prolonged use of neuromuscular blocking agents is said to leave some patients with a distal axonopathy, but this must be rare. Residual effects of polyneuropathy were seen in patients with the toxic eosinophilia-myalgia syndrome; the problem was traced to the ingestion of *adulterated* L-tryptophan which had been used in nonprescription drugs for insomnia (page 1211). One patient under our care suffered permanent areflexic quadriplegia. There may be an eosinophilic infiltrate in nerves, but the neuropathy is probably the result of a direct toxic mechanism. A sensory neuropathy resulting from excessive pyridoxine ingestion, alluded to earlier, is still seen among individuals who take huge doses of vitamin supplements. Amitriptyline is capable of producing paresthesias, but the effect seems to be idiosyncratic and infrequent.

The anesthetic agent trichloroethylene, as with the aforementioned stilbamidine, has a predilection for cranial nerves, particularly the fifth. The neurotoxicity is apparently due to dichloroacetylene, formed as a decomposition product of trichloroethylene. The neuropathic potential of nitrous oxide has already been mentioned.

**Diabetic Neuropathy**

Diabetes mellitus is the cause of the most common polyneuropathy in general clinical practice for which reason it is accorded a separate section. Several limited forms of peripheral nerve disease are also the direct result of diabetes and for convenience of exposition they are included here; some of these are acute and focal and enter into the differential diagnosis of mononeuritis multiplex considered in the next section. In recent years attention has been directed to a possible association between a nondescript sensory polyneuropathy and impaired glucose tolerance, even without manifest diabetes, persistent hyperglycemia, or elevation of the hemoglobin A-1c test. The survey by Sumner and colleagues makes a case for such an association but we remain uncertain about the relationship between glucose intolerance alone and polyneuropathy.

About 15 percent of patients with diabetes have both symptoms and signs of neuropathy, but nearly 50 percent have evidence of peripheral nerve damage as judged by nerve conduction abnormalities. The duration of diabetes is perhaps the most important factor in frequency of polyneuropathy. Somewhat fewer than 10 percent of patients have clinically evident neuropathy at the time of discovery of diabetes but this figure rises to 50 percent after 25 years. (The presence of diabetic retinopathy is also associated with a higher incidence of neuropathy.) It is not surprising, therefore, that neuropathy is most common in diabetic people older than 50 years of age; it is uncommon in those under 30 and rare in childhood. Dyck and colleagues (1993) studied 380 diabetics—27 percent with type 1 (insulin-dependent) forms and 73 percent with type 2 (noninsulin-dependent); symptomatic polyneuropathy was found in 15 percent of the first group and 13 percent of the second. The percentages were far higher when patients were selected electrophysiologically.

Several fairly distinct clinical syndromes have been delineated: (1) the most common, a distal, symmetrical, primarily sensory polyneuropathy affecting feet and legs more than hands in a chronic, slowly progressive manner; (2) acute diabetic ophthalmoplegia that affects the third, and less often, the sixth cranial nerve; (3) acute mononeuropathy of limbs or trunk including a painful thoracolumbar radiculopathy; (4) a rapidly evolving, painful, asymmetrical, predominantly motor multiple neuropathy affecting the upper lumbar roots and the proximal leg muscles (so-called diabetic amyotrophy); (5) a more symmetrical, proximal motor weakness and wasting, often without pain and with variable sensory loss pursuing a subacute or chronic course; (6) an autonomic neuropathy involving bowel, bladder, and circulatory reflexes; and (7) a painful thoracoabdominal radiculopathy. These forms of neuropathy often coexist or overlap, particularly the autonomic and distal symmetrical types and the subacute proximal neuropathies.

Most of the types of neuropathy listed above are thought to be due to ischemia or infarction of nerves or nerve fascicles, due to a diabetic microvasculopathy. All but the first are special types of *mononeuropathy multiplex*. The polyneuropathy is associated with small blood vessel disease (affecting the vaso nervorum) but possibly also with a poorly understood metabolic abnormality; however, other theories of causation abound. In recent years, an inflammatory process has been postulated as yet another mechanism of peripheral nerve damage. These aspects are discussed further on.

**Distal Polyneuropathy** The distal, symmetrical, primarily sensory form of polyneuropathy is the most common type. Although it is usually a chronic process, sometimes unnoticed by the patient, we include it here in order to provide a complete tabulation of the diabetic neuropathies. The main complaints are persistent and often distressing numbness and tingling, usually confined to the feet and lower legs, and worse at night. The ankle jerks are absent, and sometimes the patellar reflexes as well. As a rule, sensory loss is confined to the distal parts of the lower extremities, but in severe cases the hands are involved and the sensory loss may even spread to the anterior trunk, giving rise to confusion in diagnosis (Said et al). Trophic changes in the form of deep ulcerations and neuropathic degeneration of the joints (Charcot joints) are encountered.
in the most severe and long-standing cases, presumably due to sensory analgesia, trophic changes, and repetitive injury. (Foot ulcers are more common simply as a result of the microvascular disease of skin in diabetic patients.) Muscle weakness is usually mild, but in some patients a distal sensory neuropathy is combined with a proximal weakness and wasting of the types mentioned earlier. Treatment of the acral pain may be a major problem and is discussed further on.

In another group of patients with diabetic polyneuropathy the clinical picture may be dominated instead by loss of deep sensation, ataxia, and atony of the bladder, with only slight weakness of the limbs, in which case it resembles tabes dorsalis (hence the term diabetic pseudotabes). The similarity is even closer if lancinating pains in the legs, unreactive pupils, and neuropathic arthropathy are present.

**Acute Diabetic Mononeuropathies** Among these, diabetic ophthalmoplegia is a common occurrence, usually in a patient with well-established diabetes. It commonly presents as an isolated, painful third nerve palsy with sparing of pupillary function. In the first autopsy of the patient reported by Dreyfus, Adams, and colleagues, there was an ischemic lesion in the center of the retro-orbital portion of the third nerve. Subsequently, a similar case was described by Asbury and colleagues. Less often, the sixth nerve is involved. The disorder was described earlier in the chapter on page 233.

Isolated involvement of practically all the major peripheral nerves has been described in diabetes, but the ones most frequently involved are the femoral, sciatic, and peroneal nerves in about that order. Rarely is a nerve in the upper extremity affected. As mentioned, the acute mononeuropathies, both cranial and peripheral, are presumably due to infarction of the nerve but it is in studies of the third nerve that this pathologic basis has been most convincingly established as noted above. Recovery is the rule but may take many months.

**Diabetic Multiple Mononeuropathies and Radiculopathies** This category overlaps with the mononeuropathies. A syndrome of painful unilateral or asymmetrical multiple neuropathy tends to occur in older patients with relatively mild or even unrecognized diabetes. These affections of several single nerves occur in a random distribution and cause a mononeuritis multiplex. They often emerge during periods of transition in the diabetic illness, for example, when severe hyper- or hypoglycemia arises, when insulin treatment is being initiated or adjusted, or when there has been rapid weight loss. In the most characteristic type, which affects the lumbar roots, pain, which can be severe, begins in the low back or hip and spreads to the thigh and knee on one side. The discomfort has a deep, aching character with superimposed lancinating jabs, and there is a propensity for pain to be most severe at night. Weakness and later atrophy are evident in the pelvic girdle and thigh muscles, although the distal muscles of the leg may also be affected. The patellar reflex is lost on the affected side. Curiously, we have found the opposite patellar reflex to be absent in some patients. Deep and superficial sensitivity may be intact or mildly impaired, conforming to either a multiple nerve or multiple adjacent root distribution (i.e., L2 and L3) or both. Recovery is the rule although months and even years may elapse before it is complete. There is a tendency for the same syndrome to recur after an interval of months or years in the opposite leg. The EMG shows denervation in the L2–L3 and sometimes adjacent myotomes. As with the diabetic mononeuropathies, the upper extremities are only rarely affected by this process.

This form of neuropathy is often referred to as diabetic amyotrophy, a term that draws attention to one facet of the syndrome but is otherwise uninformative. Garland’s name has also been attached to this diabetic lumbar radiculoplexopathy based on his early and thorough report (but he mistakenly attributed the condition to a spinal cord lesion). A potentially vasculitic mechanism demonstrated by Raff and colleagues has been supported by PJB Dyck and others. A vasculopathy involving vaso nervorum, the traditional explanation, seems more likely to us.

Clinical experience has shown that an identical painful lumbo-femoral neuropathy may develop in nondiabetics; possibly this form is also vasculopathic or vasculitic. While lumbar disc herniation, retroperitoneal hematoma compressing upper lumbar roots, carcinomatous meningeal seeding, and neoplastic and sarcoid infiltration of the proximal lumbar plexus enter into the differential diagnosis, the diabetic type is usually so distinctive as to permit an early recognition on clinical grounds.

Also observed in diabetic patients is a syndrome of proximal symmetrical leg weakness, wasting, and reflex loss of more insidious onset and gradual evolution as discussed by Pascoe and colleagues. The iliopsoas, quadriceps, and hamstrings are involved in varying degrees. The muscles of the scapulae and upper limbs, usually the deltoid and triceps, are affected less frequently. Pain is not a consistent feature, as it is in the acute asymmetrical type, and sensory changes, if present, are distal, symmetrical, and usually mild.

In this attempt to delineate two types of proximal diabetic neuropathy, it must be emphasized that there is an overlap between them and that distal parts of a limb may be involved to a lesser degree in both conditions and that the timing of evolution of symptoms varies. Nor can the proximal and distal type be distinguished on pathologic or electrophysiologic grounds alone. Whether they should even be considered as separate entities is not clear.

Well known to diabetologists is a syndrome of thoracoabdominal radiculopathy characterized by severe pain and dysesthesia. Almost always the diabetes has been of long-standing (Kikta et al). The pain is distributed over one or several adjacent segments of the chest or abdomen; it may be unilateral or less often bilateral and tends to follow recent weight loss. Superficial sensory loss can be detected over the involved area in most patients. The pathology of this state is not known but it is also presumed to be an ischemic radiculopathy. The EMG changes consist of fibrillations of the paraspinal and abdominal muscles in one or more adjacent myotomes, corresponding to the painful area. With better control of the diabetes, or perhaps spontaneously, recovery eventually occurs but it may be protracted. The differential diagnosis includes pre-eruptive herpes zoster, sarcoid infiltration of nerve roots, and the rare entity of thoracic disc rupture.

In all forms of diabetic polyneuropathy, the CSF protein may be elevated from 50 to 150 mg/dL and sometimes even higher. The protein concentration is usually normal in cases of diabetic mononeuropathy. (Whether a slight elevation of CSF protein, discovered incidentally, can be attributed to diabetes in the absence of a polyneuropathy is uncertain.)

In this type and the ones described further on, both type 1 and type 2 diabetic patients are susceptible, the duration of diabetes being a major factor.

**Autonomic Neuropathy** Symptoms of autonomic involvement include any combination of pupillary and lacrimal dysfunction, impairment of sweating and vascular reflexes, nocturnal diarrhea, at-
Pathology and Pathophysiology  In the mundane symmetrical distal diabetic polyneuropathy, a loss of myelinated nerve fibers is the most prominent finding according to Thomas and Tomlinson. In addition, segmental demyelination and remyelination of remaining axons are apparent in teased nerve fiber preparations. The latter findings are probably too severe and widespread to be simply a reflection of axonal degeneration. Occasionally, repeated demyelination and remyelination lead to onion-bulb formations of Schwann cells and fibroblasts, as it does in the relapsing inflammatory neuropathies. Unmyelinated fibers are also reduced in number in most specimens. Similar lesions are found in the posterior roots and posterior columns of the spinal cord and in the rami communicantes and sympathetic ganglia. Under the electron microscope, the basement membranes of intraneural capillaries are seen to be thickened and duplicated. There are changes in the microvasculature of the nerves as well, similar to what is seen in other organs and in the skin as noted later.

However, substantial uncertainties persist about the pathogenesis of the diabetic neuropathies. Both the cranial (diabetic ophthalmoplegia) and peripheral mononeuropathies as well as the painful, asymmetrical, predominantly proximal neuropathy of sudden onset have been considered by most neuropathologists to be ischemic in origin, secondary to a vasculopathy of the vasa nervorum that is a property of the diabetic state. Obliterative microvascular lesions were well illustrated by Rafi and coworkers, and corresponding multiple small infarcts were found in the nerve trunks. The observations of Dyck and of Johnson and their associates have suggested that all forms of diabetic neuropathy could have the same microvascular basis. These authors described multiple foci of fiber loss throughout the length of the peripheral nerves, beginning in the proximal segments and becoming more frequent and severe in the distal segments. This pattern of change differs from that observed in diffuse metabolic disease of Schwann cells and in the dying-back type of neuropathy; i.e., the findings suggest an ischemic etiology. Fagerberg et al. had earlier noted that the fasicular capillaries and epineural arterioles have thickened and hyalinized basement membranes, similar to the microvascular changes seen in the retina, kidney, and other organs. But occlusion of vessels and frank infarction of nerve has not been observed in most cases of polyneuropathy for which reason a vascular pathogenesis remains unsettled in the minds of some pathologists.

In the past several years an alternative view has been offered, based largely on the work of PJB Dyck and colleagues and of Said and coworkers. They have found areas of perivascular inflammation and a suggestion of adjacent damage to nerve fascicles in the proximal asymmetric radicularplexus lesions. In Said’s report, this necrotizing vasculitis was observed in 6 of 22 patients and a degree of perivascular inflammation in 21, changes not seen in the typical distal sensory-motor polyneuropathy of diabetics. These findings, if valid, have implications for treatment, particularly since corticosteroids have been suggested with potential for worsening hyperglycemia. Inflammatory-vascular changes in diabetic nerves have not been as impressive in our material.

The several biochemical findings implicated in diabetic polyneuropathy and their interpretations have been reviewed by Thomas and Tomlinson and by Brown and Greene. The latter authors advance the idea that persistent hyperglycemia inhibits sodium-dependent myoinositol transport. Low levels of intraneuronal myoinositol reduce phosphoinositide metabolism and sodium-potassium ATPase activity. Others have emphasized a deficiency of aldose reductase and an elevation of polyols (particularly sorbitol) as being causally important. In reviewing these articles, one can only conclude that a convincing biochemical pathogenesis has yet to be formulated.

Another group of novel findings holds that there is a reduction in various trophic factors within diabetic nerves (NGF, VEGF, erythropoietin, etc.) and in diabetic animals, partial reversal of the polyneuropathy can be obtained by replacement of these factors through gene therapy. The work is provocative but its clinical meaning is not yet clear. Trials addressing this mode of treatment are noted later.

Treatment  The only preventive treatment is the maintenance of the blood glucose concentration at a close to normal range, since the prevailing view, derived from prolonged human studies, is that there is some relationship between peripheral nerve damage and inadequate regulation of the diabetes. This notion is supported by the findings of the National Diabetic Complications Trial, in which 715 patients with type 1 diabetes were followed for 6 to 10 years. There was a clear relation between strict glucose control, by means of an intravenous insulin infusion system, and a reduction or delay in the occurrence of painful neuropathic symptoms, retinopathy, and nephropathy. However, this came at the price of a threefold increase in hypoglycemic reactions (see also Samanta and Burden). Whether similar protective effects apply to type 2 diabetes is not known, but for most patients this degree of control is not practical.

A number of small trials have been conducted with aldose reductase inhibitors based on theoretical considerations of the above-mentioned metabolic changes (see Thomas and Tomlinson). Some recent interest has also been directed at the therapeutic use of gangliosides, which are normal components of neuronal membranes and can be administered exogenously. The authors have had no experience with either of these agents and neither one has entered routine practice.

The approach to treatment using gene therapy has been pursued in our laboratories founded by the late Dr. Jeffrey Isner. In experimental models of diabetic neuropathy the intramuscular administration of vascular endothelial growth factor (VEGF) has had a beneficial effect on several measures of nerve conduction and on the histologic changes of diabetic nerve damage in the treated limb. Whether this is mediated by a trophic influence on nerves and Schwann cells, or is the result of angiogenesis, is not known. Two trials of nerve growth factor (NGF) injections in almost 500 patients conducted by Apfel and colleagues gave equivocal results, the first being positive and the follow-up study not showing improvement. We are conducting a trial of VEGF in humans.

In the long term, the distressing paresthesias of the distal extremities are best managed with amitriptyline or one of the newer generation of antidepressants, such as sertraline or fluoxetine,
are better tolerated. Shooting, stabbing pain also responds to some degree to carbamazepine or phenytoin, but in general the results are unimpressive. Neurontin may give somewhat better results, perhaps in part because high doses are well tolerated (Gorson et al). Nerve blocks and epidural injections have been helpful in only a few patients. In the proximal asymmetrical, truncal, or ophthalmoplegic neuropathies, the severe pain usually lasts for only a short period and requires the judicious use of analgesics, as outlined in Chap. 8. Prognosis in patients with the distal, symmetrical sensory neuropathy is generally for slow progression; but in the other types improvement and eventual recovery may be expected over a period of months or years.

**ASYMMETRICAL AND MULTIFOCAL POLYNEUROPATHIES (MONONEUROPATHY, OR MONONEURITIS MULTIPLEX)**

(See Table 46-4)

Several systemic conditions may be accompanied by acute or subacute involvement of multiple individual nerves serially or almost simultaneously. This gives rise to a distinctive clinical picture that has been called mononeuropathies multiplex. The most notable examples of this syndrome are associated with polyarteritis nodosa and other vasculitides, and another not uncommon form of idiopathic vasculitis that is confined to the peripheral nervous system. The distinctive features are the acute or subacute evolution of complete or almost complete sensorimotor paralysis of single peripheral nerves, in an asymmetric distribution and not respecting proximal or distal sites and pain. Less frequently, sarcoidosis, forms of HIV-related neuropathy, and Lyme disease present in this fashion. Leprosy, a special member of this group, is discussed further on and the diabetic mononeuropathies were addressed in the preceding section.

<sup>a</sup> Possible vasculitic mechanism.

**Arteritis Angiopathic Neuropathies** Approximately half of all cases of mononeuropathy multiplex can be traced to a *systemic vasculitis of the vasa nervorum.* These are the classic causes of mononeuritis multiplex. Included in this category are polyarteritis nodosa, the Churg-Strauss syndrome (allergic bronchial asthma and eosinophilia), rheumatoid arthritis, lupus erythematosus, scleroderma, cryoglobulinemia, Wegener granulomatosis, and the aforementioned idiopathic variety of vasculitis that is confined to the cranial peripheral nerves and has no systemic manifestations. A small-vessel arteritis is also the putative mechanism in the multiple mononeuropathies that complicate Lyme disease and AIDS. In Said's series of 200 cases of vasculitis affecting the peripheral nerves, 36 percent were due to polyarteritis nodosa, 21 percent to rheumatoid arthritis, and 4 percent to other connective tissue diseases; in 35 percent there were no signs of vasculitis beyond the peripheral nerves. Elevation of the sedimentation rate and other serologic abnormalities are typical features of this entire group. This subject has been reviewed by Chalk et al; Dyck and Said; and by Kissell.

**Polyarteritis Nodosa** Perhaps 75 percent of cases of polyarteritis nodosa show involvement of the small nutrient arteries of peripheral nerves (autopsy figures), but a symptomatic form of neuropathy develops in only about half this number. Involvement of the peripheral nerves may be the principal or first clue to the diagnosis of the underlying disease when, up to that time, the main components of the clinical picture—abdominal pain, hematuria, fever, eosinophilia, hypertension, vague limb pains, and asthma—had not fully declared themselves or had been misinterpreted.

Although characteristically a disease of multiple discrete mononeuropathies, the syndrome associated with polyarteritis nodosa may appear to be diffuse and more or less symmetrical as a result of the cumulation of many small nerve infarctions, i.e., it can simulate a polyneuropathy. In these cases, careful clinical and electrophysiologic examinations disclose elements of mononeuritis that have been engrafted on an otherwise ostensibly generalized process. For example, an asymmetrical foot or wrist drop, or a disproportionate affection of one nerve in a limb, such as ulnar palsy with relative sparing of function of the adjacent median nerve, are clues. More often it takes form throughout its course of a *mononeuropathy multiplex,* i.e., a random infarction of two or more individual nerves. The onset is usually abrupt, with symptoms of pain or numbness at a focal site along a nerve or in the distal distribution of an affected nerve, followed in hours or days by motor or sensory loss in the distribution of that nerve, and then by involvement in a saltatory fashion of other peripheral nerves. Both the spinal and cranial nerves may be affected but far less often than the nerves in the limbs. No two cases are identical.

The CSF is usually normal. Nerve biopsy, usually taken from the sural nerve, will usually show the necrotizing arteritis in medium sized vessels (fibrinoid necrosis of all three coats of the vessel walls), usually with numerous infiltrating eosinophils and with occlusion of vessels. Muscle biopsy may also show perivascular inflammation and necrosis but the diagnostic yield is less than for biopsy of an affected nerve. On the basis of the smaller size of affected vessels and the presence of perinuclear antinuclear cytoplasmic autoantibodies (p-ANCA), Lhote et al have differentiated a “microscopic” polyarteritis—an entity with which we have had little experience. Rapidly progressive glomerulonephritis and lung hemorrhage are the additional features of the latter disease, neuropathy occurring somewhat less frequently than in typical polyarteritis.
Treatment Mononeuropathy multiplex due to polyarteritis calls for treatment with corticosteroids and cyclophosphamide. We have used intravenous methylprednisolone, 1.5 mg/kg, for several days, followed by oral corticosteroid treatment, and cyclophosphamide, 1 g/m² intravenously once a month for several months, but other equivalent regimens have been suggested. Azathioprine is a reasonable alternative if cyclophosphamide is not tolerated. Treatment must be continued for at least several months. In intractable cases and in those with systemic involvement, treatment with methotrexate may be indicated. Spontaneous remission and therapeutic arrest are known, but many cases have a fatal outcome from kidney and systemic complications. The infractive nerve palsies and sensory loss of the mononeuropathies generally persist to some degree even when the systemic disease is brought under control.

Churg-Strauss and Hypereosinophilic Syndrome These closely related systemic illnesses involve multiple individual peripheral nerves, much as in polyarteritis. The additional characteristic feature is an excess of circulating and tissue eosinophils (more so than in polyarteritis) and a tendency to involve the lungs and skin, in contrast to the typical renal and bowel infarctions of polyarteritis nodosa. There is, however, a considerable degree of pathologic and clinical overlap between polyarteritis and Churg-Strauss necrotizing vasculitis with asthma and vasculitic skin lesions and a more benign asthma-eosinophilia syndrome that is less aggressive and has a greater tendency for eosinophilic infiltration of other tissues. A medication (zaflurkast) that is used in Europe to treat asthma is said to have precipitated several cases of Churg-Strauss disease. Rarely, the illness has been preceded by treatment with a macrolide antibiotic (e.g., azithromycin), estrogen, and carbamazepine but these associations are uncertain and almost all cases are idiopathic.

As stated, the Churg-Strauss syndrome has many similarities to polyarteritis; indeed, the original article by Churg and Strauss in 1951 was meant in part to distinguish the two diseases on the basis of “allergic granulomas” and eosinophilic infiltrates that involved many organs. However, similar lesions within the skin and lungs have been reported from time to time in polyarteritis nodosa. Moreover, they are found in diseases such as Wegener granulomatosis, lupus erythematosus, rheumatoid disease, lymphoma, and endocarditis, but the eosinophilic infiltration is less pronounced than in Churg-Strauss syndrome. We have seen other types of cutaneous disease with vasculitic mononeuritis, the most impressive being a massive leukocytoclastic vasculitis of the skin (necrotic polymorphonuclear cells surrounding venules) resulting in large confluent hemorrhagic lesions.

In Churg-Strauss disease, rhinitis or asthma may be present for years and only later is there marked eosinophilia and organ infiltration, particularly an eosinophilic pneumonia. The neuropathy, which then develops in approximately three-quarters of patients is usually preceded by fever and weight loss and takes the form of an acute, painful mononeuritis multiplex. The granular cytoplasmic pattern of antineutrophil cytoplasmic autoantibodies (c-ANCA) of the same type that occurs in Wegener granulomatosis is found in over half of cases (see later). An infractive vasculitis involving the vasa nervorum can be detected in sural nerve biopsy, the special histologic feature possibly being a more intense eosinophilic infiltration than is usually seen in polyarteritis nodosa.

The idiopathic eosinophilic syndrome comprises a heterogeneous group of disorders, the common features of which are a persistent and extreme degree of eosinophilia and eosinophilic infiltration of many organ systems. Neuropathy occurs in less than half of the cases, taking the form of a painful diffuse sensorimotor syndrome with axonal damage or of a mononeuritis multiplex (see Moore et al). The pathologic appearance is one of diffuse infiltration of the nerves by eosinophils rather than a vasculitis. The clinical effects are attributable to the infiltration itself or to a postulated tissue-damaging effect of the eosinophilic cell.

Treatment Both the Churg-Strauss and the idiopathic hypereosinophilic syndrome are treated with high doses of corticosteroids, after which the peripheral eosinophilia as well as tissue damage abate in several weeks or months. Further immunosuppressive treatment in the form of azathioprine, chlorambucil, or cyclophosphamide has been used in fulminant or refractory cases, which includes most of the ones that we have seen.

Wegener Granulomatosis (Necrotizing Granulomatous Vasculitis) This disorder gives rise to two neuropathic syndromes—one a symmetrical or asymmetrical multiple mononeuropathy indistinguishable from the other angiopathic neuropathies described earlier, the other involving the lower cranial nerves directly as they exit the skull and pass through the retropharyngeal tissues. The frequency of peripheral nerve involvement in Wegener disease is much lower than in the other classic vasculitides. Furthermore, the affected vessels are of a smaller caliber than in polyarteritis nodosa. Nonetheless, deGroot and colleagues have emphasized in a prospective analysis of 128 patients with Wegener disease that 25 had evidence of mononeuritis multiplex with the peroneal nerve most often involved and an even greater number, with a distal polyneuropathy. The proportion of their cases in which the neuropathy was the presenting or sole manifestation of disease was higher than in other similar series. The finding of circulating c-ANCA is relatively specific for Wegener granulomatosis and for Churg-Strauss disease, as mentioned earlier (Specks et al) and helps to differentiate it from polyarteritis (which displays p-ANCA) and from carcinoma, chordoma, sarcoidosis, and zoster. This vasculitis and its effects on the lower cranial nerves is discussed further on page 1189.

Essential Mixed Cryoglobulinemia This process may be associated with a vasculitic mononeuritis multiplex as well as a more generalized polynuropathy. In many cases, glomerulonephritis, arthralgias, and purpura are conjoined, reflecting the systemic nature of the vasculopathy, but the mononeuritis may occur in isolation. The evolution in the cases under our care has been slower than in the typical vasculitic neuropathies, sometimes taking weeks or months between attacks of mononeuropathy. The neuropologic disorder may become quiescent for long periods, during which time considerable improvement may occur. There is no evident relationship between the mode of onset or severity of the neuropathy and the concentration of cryoprecipitable proteins in the serum. These proteins can be detected by cooling the serum and demonstrating a precipitation of IgG and IgM proteins that redissolve upon warming to 37°C (98.6°F). To demonstrate this phenomenon the blood sample must be carefully transported to the laboratory in a warm water bath. An association with hepatitis C is well known but most patients with cryoglobulinemia have manifested mononeuritis without this infection.

Treatment Garcia-Bragado and colleagues have suggested that the neuropathy can be stabilized by corticosteroids and cyclophosphamide. In our experience, plasma exchange has also been beneficial, but this therapeutic measure has not been systematically tested. Other aspects of the condition are discussed further under
“Polyneuropathy Associated with Paraproteinemia” and under “Other Vasculitic Neuropathies.”

Rheumatoid Arthritis Some 1 to 5 percent of patients with rheumatoid arthritis have vasculitic involvement of one or more nerves at some time in the course of their disease, apart from more mundane pressure neuropathies due to thickened tendons and destructive joint changes. The arteritis is of small-vessel fibrinoid type and immune globulins are demonstrable in the walls of vessels. Most of the affected patients have had severe rheumatic disease for many years and are strongly seropositive. In addition to the neuropathy, such patients often have rheumatoid nodules, skin vasculitis, weight loss, fever, a high titer of rheumatoid factor, and low serum complement.

There are also rarer forms of chronic progressive polyneuropathy that complicate rheumatoid arthritis; they are described further on.

Lupus Erythematosus Approximately 10 percent of patients with lupus will exhibit symptoms and signs of peripheral nerve involvement. Usually the neuropathy appears in the established and more advanced stages of the disease, but rarely it has been the initial presentation. In several of our cases the polyneuropathy has taken the form of a symmetrical, progressive sensorimotor paralysis, beginning in the feet and legs and extending to the arms, evolving over a period of several days or weeks and at times simulating GBS. In a few, weakness and areflexia were more prominent than the sensory loss; the latter involved mainly vibratory and position senses. A more common syndrome in our experience has been a progressive or relapsing disease that cannot be distinguished clinically from chronic inflammatory demyelinating polyneuropathy (discussed further on). Multiple mononeuropathies have also been reported, as has involvement of the autonomic nervous system. An elevation of CSF protein in some cases suggests nerve root involvement. Sural nerve biopsies may show vascular changes consisting of endothelial thickening and mononuclear inflammatory infiltrates in and around the small vessels for which reason the disease is included here with the other vasculitic neuropathies. Axonal degeneration is the most common change, but a chronic demyelinating pathology has also been described (Rechthand et al.). Vascular injury from deposition of immune complexes is the proposed mechanism of nerve damage.

Isolated (Nonsystemic) Vasculitic Neuropathy In contrast to the aforementioned disorders, which characteristically involve several tissues and organs in addition to the peripheral nerves, a necrotizing vasculitis may be limited to nerves. In our hospitals a case of this type appears about twice a year, i.e., about as often as all the other systemic vasculitic types put together. This restricted form usually presents as a subacute symmetrical or asymmetrical polyneuropathy with superimposed mononeuropathies or with multiple mononeuritis; circulating ANCA is found in some cases. It is notable that in the series reported by Collins and colleagues, the sedimentation rate was generally only mildly elevated, the mean being 38 mm/h, with only one quarter having values greater than 50 mm/h. The neuropathy tends to be indolent and less aggressive (and nonlethal) than the systemic forms of vasculitic neuropathy and has not always required treatment with cyclophosphamide (Dyck et al., 1987). Steroids in high doses have prevented progression of the disease. However, in the aforementioned series by Collins, the use of cyclophosphamide for 6 months with corticosteroids resulted in a more rapid remission and fewer relapses. The main difficulty in diagnosis arises when the EMG performed early in the course of illness shows conduction block that simulates a demyelinating polyneuropathy. Nerve biopsy should then settle the issue.

Other Vasculitic Neuropathies In the past, administration of pooled serum for the treatment of infections often led to brachial neuritis (page 1163) and also to an immune mononeuritis multiplex, presumably from deposition of antibody-antigen complexes in the walls of the vasa nervorum. A similar “serum sickness” may occur after certain viral infections that have caused arthritis, rash, and fever. The neuropathy that arises with hepatitis C infection may also be of this type, perhaps mediated by a frequently associated cryoglobulinemia as mentioned earlier. Interferon, which has been effective in treating the hepatitis, may also ameliorate the neuropathy, but greater success has been achieved with cyclophosphamide. Pooled immunoglobulin for the treatment of diverse neuromuscular diseases has not, to our knowledge, led to a serum sickness neuropathy, but one of our patients with Churg-Strauss disease developed a fulminating vasculitic skin eruption while being treated with IVIG.

In two cases of severe systemic vasculitis related to administration of hydralazine, we observed no neuropathic features; whether this applies to other drug-induced vasculitides is not known. The increasing appearance of vasculitic neuropathy with HIV infection, including a type that is probably independent of CMV infection, has already been mentioned; such cases have tended to improve spontaneously or with corticosteroid therapy. In about half of these cases of this type the CSF shows a predominance of polymorphonuclear cells. Also, from time to time a patient with a lymphoproliferative disorder such as Hodgkin disease will develop mononeuritis multiplex that is found by biopsy to be due to vasculitis. (A chronic demyelinating, nonvasculitic polyneuropathy is more common with lymphomas of any type as discussed earlier.)

A rare paraneoplastic variety of vasculitic neuropathy has been described. Oh reported two of his own cases and reviewed 13 previous ones. The most common underlying cancer was of the small oat cell lung type. The anti-Hu antibodies that are typical of paraneoplastic neurologic diseases from this cancer are generally not detected. Other solid tumors (renal, gastric, etc.) have been associated with a similar neuropathy but only in a few instances. Almost all have a slightly elevated protein concentration in the CSF, but few had a pleocytosis. At autopsy, the vasculitis was limited to nerve and muscle.

The role of small-vessel vasculitis in obscure axonal polyneuropathies of elderly patients is controversial. We have not found, as did by Chia and colleagues, an unexpected vasculitis in the nerve biopsies of such patients. The vaso-occlusive and infiltrative condition of intravascular lymphoma often includes a syndrome of multiple painless mononeuropathies.

Neuropathy Due to Critical Limb Ischemia A number of patients with severe atherosclerotic ischemic disease of the legs will be found to have localized sensory changes or impairment of reflexes. Usually the other effects of ischemia—claudication and pain at rest, absence of distal pulses, and trophic skin changes—are so prominent that the neurologic changes are overlooked. In experimental studies, combined occlusion of the aorta and many limb vessels are required to produce nerve ischemia because of the profusely ramifying neural vasculature. In our experience of
12 patients with a critically ischemic leg, there was a neuropathy with a pronounced distal predominance—sensory loss in the feet was worse than the symptoms might suggest and there was only mild weakness of the toes and depression or loss of the ankle reflex (Weinberg et al). Although paresthesias, numbness, and deep aching pain were characteristic, the patients were more limited by symptoms of their vascular claudication than the neuropathic ones. Restoration of circulation to the limb by surgical or other means resulted in some improvement of the regional neuropathy. Reviews of the literature on this subject are to be found in the writings of Chalk et al and Eames and Lange.

A poorly understood but presumably localized ischemic neuropathy occurs in the region of arteriovenous shunts that have been placed for the purpose of dialysis. Complaints of transient diffuse tingling of the hand are not uncommon soon after creation of the shunt, but only a few patients develop persistent forearm weakness and numbness and burning in the fingers, reflecting variable degrees of ulnar, radial, and median nerve and possibly also muscle ischemia. The possible role of an underlying uremic polyneuropathy in facilitating this neuropathy has not been studied.

A progressive, symmetrical polyneuropathy due to systemic cholesterol embolism has been described by Bendixen and colleagues. An inflammatory and necrotizing arteritis surrounds embolic cholesterol material within small vessels and appears to account for the progression of symptoms. This neuropathic process is probably more often discovered at autopsy than it is in the clinic, being eclipsed during life by the cerebral manifestations of cholesterol embolism. The entire illness simulates the generalized polyneuropathy of a small-vessel polyarteritis.

**Sarcoidosis** Sarcoidosis infrequently produces subacute or chronic polyneuropathy, polyradiculopathy, or mononeuropathies. A painful, small-fiber sensory neuropathy has also been described by Hoitsma and colleagues. Either type of neuropathy may be associated with granulomatous lesions in muscles (polymyositis) or with signs of CNS involvement, most often of the stalk of the pituitary with diabetes insipidus or a myelopathy.

Involvement of a single nerve with sarcoid most often implicates the facial nerve (facial palsy), but sometimes multiple cranial nerves are affected in succession (see page 1183). Or, there may be weakness and reflex and sensory loss in the distribution of one or more spinal nerves or roots. The occurrence of large, irregular zones of sensory loss over the trunk is said to distinguish the neuropathy of sarcoidosis from other forms of mononeuropathy multiplex. This type of sensory loss, particularly when accompanied by pain, resembles diabetic radiculopathy (see earlier).

Unlike the cases we have reported (Zuniga et al), in the series of 11 patients with sarcoid neuropathy studied by Said and colleagues, only 2 were known to have pulmonary sarcoidosis before the onset of neuropathic symptoms. Six had a focal or multifocal syndrome (including one with a clinical and electrophysiologic pattern that simulated multifocal conduction block). The remainder had a more nondescript symmetric polyneuropathy, one of acute onset. Facial diplegia was common, as is well known. The pathologic changes in nerve and muscle biopsy specimens consisted mainly of epineurial granulomas and endoneurial inflammatory infiltrates, but there were indications of necrotizing vasculitis in 7 cases. Among the cases we studied, 6 of 10 had a subacute or chronic sensorimotor polyneuropathy. It is notable that in only 2 of their patients were levels of angiotensin-converting enzyme elevated in the serum.

**Lyme Disease** (See also page 618) The neuropathy that develops in 10 to 15 percent of patients with this disease takes several forms. Cranial nerve involvement is well known, uni- or bilateral facial palsy being by far the most frequent manifestation (page 1182). Other cranial nerves are from time to time also affected and the disease may affect almost any of the somatic roots, most evident in the cervical or lumbar ones. Even phrenic nerve palsy has been attributed to Lyme disease in a few cases. An aseptic meningo-radiculoitits giving rise to a pleocytosis is particularly characteristic (although this may also occur in HIV and CMV and other forms of neuritis). Some of the CSF cells at times have immature features suggesting a lymphomatous infiltration. There may be radicular pain not unlike that of cervical or lumbar disc or plexus disease. The triad of cranial nerve palsies, radiculitis, and aseptic meningitis is characteristic of Lyme disease during its disseminated phase, i.e., from 1 to 3 weeks after the tick bite or the appearance of the typical rash. The disease tends to be seasonal in the period of maximal tick exposure. As to peripheral neuropathy with Lyme disease, the clinical situation is more complex. Several patterns of neuropathy have been recognized and they tend to appear some months after the Lyme infection and may last for years hence observing no seasonal pattern.

Besides the previously described cranial neuropathies, the following are the main neuropathic syndromes of Lyme disease: (1) multiple mononeuropathies (involvement of a single major nerve in the limbs, resulting in an isolated foot or wrist drop, is, however, distinctly rare); (2) a lumbar or brachial plexopathy (the latter being well described but rare); (3) a predominantly sensory polyneuropathy in which paresthesias and loss of superficial sensation in the feet and legs are coupled with loss of ankle jerks; (4) a generalized axonal polyneuropathy (Loggigian et al), mainly sensory and sometimes accompanied by a mild encephalopathy; and (5) acute GBS (we have encountered only two such cases in over 400 patients with Guillain-Barré). Electrophysiologic testing indicates that the various peripheral nerve syndromes frequently overlap. All of the preceding processes excepting the one that resembles GBS usually occur as subacute or late complications of Lyme disease, several months or rarely years after the initial infection (in untreated cases). These later neuropathic syndromes respond less favorably to treatment than do the acute ones (see further on).

There are few adequate pathologic studies of the peripheral nerves in Lyme disease, since the disease is not fatal. No one has demonstrated the infective agent in the nerves, although this has been one of the suggested targets of disease.

**Bannwarth Syndrome** Special mention is made of an intensely painful lumbosacral polyradiculitis that has long been known in Europe under the term *Bannwarth syndrome* (in France it is known as Garin-Bujadoux syndrome). The pathogen is probably a spirochete slightly different from the one that causes Lyme disease in North America. In the Bannwarth syndrome, and in occasional cases of otherwise typical Lyme disease, there is an intense inflammatory reaction in the cauda equina giving rise to sciatic and buttock pain and bladder disorder. Less frequently a cervical polyradiculopathy occurs with shoulder and arm pain that we have been unable to distinguish on clinical grounds from brachial neuritis. The EMG, however, shows a preservation of sensory potentials, which marks the process as radicular rather than plexal (see further on). Headache and a brisk pleocytosis in the spinal fluid may accompany the pain and usually precedes radiculopathies by days. It should be commented that a similar syndrome of lumbar polyradiculitis may also be caused by the herpes and Epstein-Barr viruses.
or more often by an opportunistic CMV infection in a patient with AIDS.

**Diagnosis**  This is both aided and at times confused by serologic testing (see Chap. 32). The enzyme-linked immunosorbent assay (ELISA) is not altogether satisfactory because it frequently yields false-positive and, occasionally, false-negative results. Western blot testing is more specific. Knowledge that the patient has lived in or visited an endemic area is useful but far more important is evidence of a tick bite followed by the characteristic rash or a well-defined history of nonneurologic manifestations of Lyme disease (cardiac, arthritic). Indeed, one should be cautious in making this diagnosis unless a primary Lyme infectious syndrome had been present. Bifacial palsy in any of these clinical contexts also favors the diagnosis.

**Treatment**  Treatment of the neuropathic disease is with intravenous antibiotics, preferably ceftriaxone 2 g daily for 1 month. Corticosteroids have an uncertain role in the painful radicular syndromes but we have used them in low doses and they apparently relieved the pain.

**Sjögren-Sicca Syndrome**  This is a chronic, slowly progressive autoimmune disease characterized by lymphocytic infiltration of the exocrine glands, particularly the parotid and lacrimal glands resulting in keratoconjunctivitis sicca and xerostomia (dry eyes and mouth). The latter features may be combined with arthritis or with a wide range of other abnormalities, notably lymphoma, vasculitis, renal tubular defects, and quite often by a predominantly sensory polyneuropathy (see review by Kaplan et al.). In the series collected by Grant and colleagues, the neuropathy was the presenting problem in 87 percent of 54 patients with the sicca complex. The sicca symptoms are usually mild and often reported only upon specific inquiry. A symmetrical sensory polyneuropathy or sensory ganglionopathy is the most common pattern. Sensorimotor polyneuropathy, polyradiculoneuropathy, autonomic neuropathy, or mononeuropathy (most often of the trigeminal nerve, as described by Kallieried and Talal) are less common. We have observed yet another neuropathic syndrome taking the form of an asymmetrical sensory loss, mostly of position sense and involving the upper limbs predominantly, in association with tonic pupils and trigeminal anesthesia.

The sensory polyneuropathy of the Sjögren syndrome—more of an inflammatory ganglionitis or sensory neuronopathy (Griffin et al.)—is of particular interest to neurologists, since most cases will first be seen by them. More than 90 percent of the patients are older women. The sensorimotor polyneuropathic syndrome begins with paresthesias of the feet and is usually mild in degree. The main clinical features are a subacute and widespread sensory loss that may include the trunk and a profoundly diminished kinesthetic sense, giving rise to sensory ataxia of the limb and of gait. Loss of pain and temperature sensation is variable; tendon reflexes are abolished. In time, many of these patients develop autonomic abnormalities such as bowel atony, urinary retention, loss of sweating, and pupillary changes. There is usually little or no pain but there have been exceptions.

**Diagnosis**  Sjögren syndrome should be suspected in an older woman with sensory neuropathy or neuronopathy, particularly if sicca symptoms are present. The evaluation of suspected Sjögren disease is aided by the Schirmer or Rose Bengal tests (page 461), which can demonstrate a reduction of tearing. Even without this confirmatory test, we have found it advisable to perform a biopsy of the lip (at the epithelial-mucosal juncture) to detect inflammatory changes in the small salivary glands. This is a minor office procedure in most instances. The diagnosis of Sjögren syndrome requires the detection of at least two collections of 50 or more lymphocytes in a 4 mm² specimen. Some patients have serologic abnormalities such as antinuclear antibodies (anti-Ro, also termed SS-A, and anti-La, or SS-B) or increased monoclonal immunoglobulins, particularly of the IgM subclass. The frequency of these specific Sjögren-specific antibodies varies greatly between series; they may be useful as screening tests, but the lip biopsy is a far more sensitive diagnostic procedure. In our series of 20 cases with salivary gland biopsies that demonstrated inflammatory changes diagnostic of the syndrome, only 6 had serologic evidence of the disease and two had positive serologic tests but a negative biopsy (Gorson and Ropper). The sedimentation rate in our patients was often slightly elevated, however, only 5 of our 20 had a value greater than 40 mm/min. The main differential diagnostic entity is a paraneoplastic sensory ganglionitis.

Mellgren and also Leger and their colleagues have stressed the point that a proportion of unexplained polyneuropathies in middle and late life are caused by Sjögren syndrome. The latter authors found typical Sjögren abnormalities in the lip biopsies of 7 of 32 patients with chronic axonal polyneuropathy that could not otherwise be classified. Several other studies have corroborated this finding of inflammatory disruption of the minor salivary glands in obscure neuropathies, particularly in older women and in some men. The diagnosis in our clinics, where lip biopsies are routinely performed in patients with nondescript sensory neuropathies, has not been nearly as frequent. Nonetheless, a search for Sjögren disease may be revealing in otherwise obscure sensory neuropathies.

Nerve biopsies in some cases have revealed a necrotizing vasculitis, inflammatory cell infiltrates, and focal nerve fiber destruction. Usually, the CSF protein is normal and there is no cellular reaction. The few times a dorsal root ganglion has been examined, there were infiltrates of mononuclear cells and lymphocytes and destruction of nerve cells.

**Treatment**  Treatment of the sicca complex and the neuropathic manifestations is fortunately largely symptomatic. Corticosteroids, cyclophosphamide, and chlorambucil have been used when the neuropathy is severe and are indicated when there is vasculitis involving renal and pulmonary structures. We have administered prednisone 60 mg daily, often in tandem with intermittent plasma exchange, with little evidence of response. In a few severe cases, monthly intravenous cyclophosphamide has been added. Others have recorded more encouraging results.

The review of the neurologic manifestations of Sjögren syndrome by Lafitte is recommended.

**Idiopathic Sensory Ganglionopathies (Chronic Ataxic Neuropathy)**  In addition to the subacute pansensory syndrome described above and paraneoplastic, postinfectious, or toxic processes (page 1128), there is a more chronic idiopathic variety characterized by severe global sensory loss and ataxia. We have encountered several such patients with sensory loss and pronounced ataxia resembling the cases described by Dalakas. The numbness and sensory findings progressed over months and spread to proximal parts of the arms and legs and then to the trunk. The face and top of the scalp were finally involved. Despite severe ataxia and complete areflexia, muscular power remained normal. Pain was not a problem. There are reports of fasciculations in a few patients (but not in the ones we have seen). Within a year, most of these patients became completely disabled from the ataxia, unable to walk or even...
feed themselves. Autonomic failure was another feature in a few, and one of ours became deaf. Extensive examinations for an occult cancer, paraproteinemias, Sjögren disease, Reifsmann disease, autoimmune diseases, and all potential causes of an ataxic neuropathy, proved to be frustratingly negative. Of course, it is possible that some patients had an as yet undiscovered tumor. Yet other instances have had all the features of a truncal-limb sensory neuropathy, with little or no ataxia and only muted reflexes; these have had a more benign course but still no cause was found (why most of our patients have been male physicians, as reported by Romero, is entirely unclear). Illa and colleagues, in a review of 17 patients with idiopathic sensory ataxic neuropathy found antibodies against the ganglioside GD1, in only one case, and concluded that the majority were not due to an immunologic mechanism.

The motor nerve conduction studies have been normal or slightly impaired, while the sensory potentials were eventually lost (but they may at first be normal). A puzzling feature in two patients has been an unexpected preservation of many sensory nerve potentials even after a year of illness. In these cases the process presumably lay in the dorsal roots rather than in the ganglia. In a few instances the MRI has shown a change in the posterior columns of the spinal cord, presumably secondary to root disease. The spinal fluid has generally contained a slightly elevated protein concentration with few or no cells, up to 18/mm³ in our cases.

Pathologic examination of the sensory ganglia in a few cases has exposed an inflammatory process identical to that of Sjögren disease. Our attempts at treatment using plasma exchanges, IVIG, corticosteroids, and immunosuppressive agents have been mostly unsuccessful.

### Idiopathic Autonomic Neuropathy

Under this term is collected a group of dysautonomias that on extensive evaluation cannot be attributed to diabetes or amyloidosis. A fair number, almost half in the series of Suarez and colleagues, are acute in onset and conform to the “pure pandysautonomia” condition described by Young and colleagues and discussed earlier as a variant of GBS. The others, however, pursue a subacute or chronic course and about one quarter of these has an associated serum antibody that is directed against the acetylcholine receptor of sensory ganglia (Klein et al). Orthostatic hypotension is the leading feature and in those with the previously mentioned antibody, pupillary changes and difficulty with accommodation, dry mouth and dry eyes, and gastrointestinal parasympathetic pseudocyeses were the most common findings according to Sandroni and colleagues. Perhaps another subgroup is in some way related to Sjögren syndrome since sicca symptoms are prominent but these later features could just as well be a component of the autonomic failure and the appropriate antibodies have been found only rarely.

There is not enough information to determine if all these cases are accounted for by one process or to judge the effects of various immune treatments.

### Migrant Sensory Neuritis (Wartenberg Syndrome)

The defining feature of this syndrome is a searing and pulling sensation involving a small cutaneous area of a limb evoked by extending or stretching the limb, as happens when reaching for an object with the extended arm and hand, or when kneeling, or pointing with the foot. The pain is momentary but leaves in its wake a patch of numbness. Cutaneous sensory nerves must be involved in some way and are irritated during such a maneuver. Often the area involved is proximal to the most terminal sensory distribution of the nerve, encompassing, for example, a patch on the lateral side of the hand and the proximal fifth finger or a larger region over the patella (the sites affected in three of our patients). Recovery of the patch of numbness takes several weeks but it may persist if the symptoms are induced repeatedly. Except for these patches of cutaneous analgesia, the clinical examination is normal. Selected sensory nerves may show abnormalities in conduction. Matthews and Esiri have listed the many areas that may be affected in a single patient and have described an increase in the endoneurial connective tissue in a biopsied sural nerve. The process may come in episodes over many years, without symptoms between attacks. A spurious diagnosis of multiple sclerosis is often made. The pathology is not known but some form of fibrosis or inflammation of cutaneous nerves has been suggested, perhaps in some way similar to the condition described below.

### Sensory Perineuritis

Under this title, Asbury and colleagues described a patchy, painful, partially remitting distal cutaneous sensory neuropathy. The pathologic picture was one of inflammatory scarring restricted to the perineurium, with compression of the contained nerve fibers. As with the Wartenberg syndrome earlier, the reflexes and motor function were unaffected. Digital nerves as well as the medial and lateral branches of the superficial peroneal nerve were the ones most often involved. Matthews and Squier have described a trigeminal and occipital distribution of painful sensory symptoms, and one of the patients of Asbury and coworkers also had symptoms on the scalp. A Tinel sign is characteristically elicited by tapping the skin overlying the involved cutaneous nerves and is indicative of partial nerve damage and regeneration. The differential diagnosis includes numerous other forms of painful sensory neuropathy but the patchy and painful and often burning quality of symptoms distinguishes this process. The diagnosis can only be established with certainty by biopsy of a distal cutaneous branch of a sensory nerve. Perhaps some of the large group of patients with “burning” feet may have a small-fiber neuropathy that affects intradermal nerve fibers in a similar way (see further on).

Since the original report, the fibrosing perineurial pathologic changes that characterize perineuritis have been described in a number of polyneuropathies, mainly in diabetic patients but also in those with cryoglobulinemia, nutritional diseases, and malignancies (Sorensen et al). However, these patients displayed a diversity of clinical patterns of neuropathy, mainly mononeuritis multiplex and demyelinating neuropathy. These findings indicate that the pathologic feature of perineuritis may be less specific than initially thought but the perineuritis clinical syndrome is still a useful concept. A proportion of the idiopathic cases respond to corticosteroids.

### Celiac-Sprue Disease

Among the multitude of odd neurologic manifestations attributed to this disease (see pages 977 and 1001) the best known are a cerebellar ataxia and myoclonus. In addition, Hadjiavassi and colleagues have reported patients with a range of neuromuscular disorders in whom the neurologic symptoms antedated the diagnosis of the bowel disorder. A nondescript sensorimotor neuropathy was the most frequent complication, but one patient was said to have a mononeuritis multiplex. In a small prospective survey of treated celiac disease, Luostarinen and colleagues found 23 percent with evidence of a polyneuropathy by EMG testing but the clinical findings were scant. Antigliadin antibodies (simple antibodies directed against gluten), as well as more specific antigliadinase antibodies and histologic examination of a duodenal biopsy are confirmatory of the diagnosis. Luos-
tarinen et al have suggested that a search be made for these antibodies in patients with polyneuropathies of obscure origin. It is not clear how many of their cases could be attributed to nutritional deficiency. We have not encountered a definite case despite systematic attempts to detect the special antibodies in the evaluation of obscure neuropathies.

Numerous other systemic diseases have reportedly been conjoined with peripheral neuropathy, among them, temporal arteritis. In most of these anecdotal reports it is impossible to interpret etiologic relationships.

**Syndrome of Polyradiculopathy with or without Meningeal Infiltration**

These are among the most clinically complex diseases of the peripheral nerves. Involvement of multiple spinal nerve roots produces a distinctive but sometimes confusing constellation of findings, usually quite different from those of polyneuropathy and from multiple mononeuropathies. As described earlier, muscle weakness due to polyradiculopathy is characteristically asymmetrical and variably distributed in proximal and distal parts of the limbs, reflecting the fact that the involved muscles have a common root innervation (for example, the combination of hamstring and gastrocnemius, or of iliopsoas, quadriceps, and obturator). However, muscles with similar innervation are not necessarily affected to the same degree because of the disproportionate contribution of a given root to each muscle it supplies. Sensory loss tends also to be similarly patchy and to involve both the proximal and distal aspects of a dermatome. As a rule, pain is common (though not invariably) while the sensory findings tend to be less prominent than the motor ones. In keeping with nerve root pattern, certain tendon reflexes may be spared; a normal ankle jerk combined with an absent knee jerk, or the opposite, are particularly suggestive of a polyradiculopathy (or a lumbar plexopathy). Pain often takes the form of sharp jabs projected into the innervated zone of the involved root. As with mononeuritis multiplex, the cumulative effect of multiple root lesions can simulate a polyneuropathy in which case the tendency for polyradiculopathy to involve proximal muscles is the most helpful distinguishing feature.

A special pattern of polyradiculopathy may occur wherein all the sensory roots are involved diffusely. The clinical state is similar to that of a sensory ganglionopathy described earlier. Large- and small-fiber sensory loss is combined with ataxia while power is normal and there is no atrophy. A prominent feature is shooting and burning pain. We have also occasionally found sensory loss over the anterior abdomen and thorax, a finding more typical of chronic dying-back axonal polyneuropathy.

Some of the diseases that affect nerve roots solely or predominantly have already been discussed. They can be grouped into three broad categories: (1) diseases of the spinal column that compress adjacent roots; (2) infiltrative diseases of the meninges that secondarily involve the roots as they course through the subarachnoid space, including neoplastic granulomatous infiltration; and (3) intrinsic neuropathies, usually inflammatory, infectious, or diabetic, that have a predilection for the radicular portion of the nerves. An elevated CSF protein and a pleocytosis usually accompany neoplastic or inflammatory meningeal diseases; the others show variable formulas in the spinal fluid.

Often what appears to be a polyneuropathy on clinical grounds turns out to have an electrophysiologic pattern of root disease at multiple spinal levels. McGonagle and colleagues estimated that polyradiculopathies accounted for 5 percent of all cases referred to their EMG laboratory and our experience approximates this. Careful EMG testing is therefore the most useful ancillary examination in cases of complex neuropathic syndromes since the pattern of muscle denervation can be ascertained and a common root pattern can then be logically derived. Of great confirmatory value is the preservation of sensory potentials in nerves that innervate regions of sensory loss and supply weak and denervated muscles. This proves that the lesion is located proximal to the dorsal root ganglion and spares the peripheral sensory axons. Loss of the F and H late responses is also typical of polyradiculopathies (see page 1100). The proximal location of the lesion can be further corroborated by early evidence of weakness and denervation in the paraspinal, gluteal, or rhomboid muscles, which are supplied by nerves that arise very proximally from the roots. In axonal neuropathy, these proximal muscles are the last to be involved.

Among the acute and subacute meningeal radiculopathies, neoplastic infiltration (carcinomatous and lymphomatous) is the most common. Others are Lyme disease, sarcoidosis, herpes genitalis, arachnoiditis, AIDS-related cauda equina neuritis of CMV infection, or independently by EBV. In the past, meningeal syphilis was a common cause. Diseases of the spine, exemplified by lumbar and cervical spondylosis, commonly impinge on nerve roots, as discussed in Chap. 11. Metastatic carcinoma of the vertebral bodies may compress one or several adjacent roots by encroaching on posterolateral recesses of the canal and proximal neural foramina. Among rarer causes of polyradiculopathy is a chronic lumbosacral syndrome associated with dural evaginations surrounding nerve roots which may complicate ankylosing spondylitis (see page 180).

Finally, it should be mentioned that one is confronted not infrequently by a subacute or chronic polyradiculopathy and abnormal CSF formula, for which extensive examination fails to identify any one of the diseases enumerated above. This idiopathic form of polyradiculopathy comes to our attention once or twice yearly. Some will turn out to have a lymphomatous infiltration at autopsy for which reason we have on occasion asked our neurosurgeons to remove a midlumbar motor rootlet for examination. Also particularly difficult diagnostically is a polyradiculopathy that involves the motor roots exclusively or predominantly that is distinguishable from motor neuron disease except for the complete absence of widespread denervation or of progressive upper motor neuron signs and, differing from the immune motor neuropathies discussed further on, by the absence of conduction block.

**SYNDROME OF CHRONIC SENSORIMOTOR POLYNEUROPATHY**

In these syndromes, impairment of sensation, weakness, muscular atrophy, and loss of tendon reflexes progress over a period of many months or years. Within this large category, two groups are distinguished. In the first and less chronic of the two groups the neuropathy develops over a period of months or a year or two. Comprising this group are mainly acquired processes such as certain metabolic and immune-mediated polyneuropathies. Paraneoplastic neuropathies may also fall into this category though they are more often subacute in onset, being almost fully developed in a matter of months or less. Leprous neuritis is the one infectious member of this group and also the one exception to the rule that all chronic neuropathies are more or less symmetrical in pattern. The polyneuropathies that make up the second group are far more chronic than...
the first, evolving insidiously over many years or decades. Constituting this second group are mainly the *heredodegenerative* diseases of the peripheral nervous system.

**Acquired Forms of Chronic Polyneuropathy**

### Polyneuropathy Associated with Paraproteinemia

The occurrence of a chronic sensorimotor polyneuropathy in association with an abnormality of serum immunoglobulins is recognized with increasing frequency but its boundaries are still not well established as will be apparent in the following discussion. The excess blood protein, called a *paraprotein*, or an M-spike is usually in the form of a monoclonal immunoglobulin. It may be an isolated abnormality or a by-product of a plasma cell malignancy, specifically multiple myeloma, plasmacytoma, or Waldenstrom macroglobulinemia. Several lines of evidence suggest that a pathogenetically active antibody against components of myelin or axon is present in at least some of these diseases. Special forms of neuropathy are also associated with amyloidosis. Both the acquired and genetic forms of amyloidosis are discussed further on.

**Monoclonal Gammopathy of Undetermined Significance (MGUS, Benign Monoclonal Gammopathy)**

The association of a nonneoplastic IgM monoclonal protein and a neuropathy was first described by Forssman and colleagues and was treated as coincidental until Kahn established a compelling statistical association between them. A more direct relationship was established by the finding of antiperipheral nerve antibodies in some patients who had such a protein in their blood. This important category of polyneuropathy is associated with a nonneoplastic monoclonal or polyclonal excess of immunoglobulin (IgG, IgM, or IgA, rarely others; see reviews of Kyle and Dyck and of Thomas and Willison). These cases are far more common than those with malignant plasma cell disorders. In our experience, monoclonal proteins underlie the largest group of otherwise unexplained neuropathies in adults.

The polyneuropathy associated with monoclonal gammopathy affects mainly, but not exclusively, males in the sixth and seventh decades of life. The onset is insidious over weeks or months with numbness and paresthesias of the feet and then of the hands, followed by a relatively symmetrical weakness and slight wasting of these muscles over a year or so. In some patients sensory signs predominate. The tendon reflexes, eventually lost or diminished, may be preserved in the early phases of the illness. The course is usually slowly progressive, sometimes static after a year or so and rarely remitting and relapsing. The CSF typically shows an elevation of the protein in the range of 50 to 100 mg/dL and this is not due to passive diffusion of the excess paraprotein into the CSF.

The majority of cases of polyneuropathy with monoclonal gammopathy have a demyelinating or mixed axonal-demyelinating pattern in the EMG, but once the illness is well established most will have predominantly axonal features. With the exception of somewhat less sensory loss and preserved or reduced tendon reflexes (the latter in some axonal cases) we have been unable to distinguish the axonal and demyelinating groups on clinical grounds or by their response to therapy (Gorson, Ropper, et al). Sural nerve biopsies show a loss of myelinated fibers of all sizes; unmyelinated fibers are mostly spared; hypertrophic changes, reflecting cycles of demyelination and remyelination with fibrosis are present in about half the cases according to Smith et al. They found the monoclonal IgM antibody bound to surviving myelin sheaths, and Latov and coworkers have shown that the serum IgM fraction often displays anti-myelin activity.

Typically, the monoclonal protein in the blood is present in a concentration less than 2 g/100 mL and there is no evidence of multiple myeloma or other malignant disease. It should be emphasized that routine serum protein electrophoresis (SPEP) fails to detect the majority of these paraproteins; immunoelectrophoresis (IEP) or the more sophisticated immunofixation testing is required. The bone marrow aspirate shows a normal or only mildly increased proportion of plasma cells, which are the ostensible source of the paraprotein, and the plasma cells are not morphologically atypical, as they are in myeloma. Insofar as myeloma becomes manifest in fewer than one quarter of patients many years after the gammapathy has been recognized, the condition is now termed *monoclonal gammapathy of undetermined significance* (MGUS), although the older term, benign monoclonal gammapathy, is less cumbersome.

The importance of excess immunoglobulin can be appreciated by noting that some 6 percent of patients referred to the Mayo Clinic with chronic polyneuropathy of unknown cause and as many as 20 percent in our clinical material and in other series have proved to have a monoclonal paraproteinemia (of course, the majority of patients with a blood paraprotein do not develop neuropathy). Despite the fact that IgG is the most frequent paraprotein in adults, a polyneuropathy is associated somewhat more often with the IgM class. Combining three large series of patients with neuropathy and monoclonal paraproteinemias (62 patients of Yeung et al, 65 patients of Gosselin et al, and 34 of our patients reported by Simovic et al), there were 96 with IgM, 50 with IgG, and 15 with IgA subclass paraproteins. An identical but infrequent condition exists in which only the light chain component of an immunoglobulin is overproduced by the plasma cells and is found exclusively in the urine (similar to the Bence-Jones protein of multiple myeloma).

Most affected patients have had a *kappa* light chain component although *lambda* light chain has special significance as discussed further on in relation to plasmacytoma and the “POEMS” syndrome. In our experience and in that of others, the group with IgM paraprotein has more often displayed severe sensory findings and a demyelinating type of EMG abnormality when compared with the IgG group. However, with the exception of the special anti-myelin-associated glycoprotein (MAG) syndrome (see later), we have not found the degrees of difference in clinical features and response to treatment between the immunoglobulin subclasses that has been reported by others (Simovic et al).

Although more than a dozen specific antibodies against myelin and other components of nerve have been identified among the paraproteins, the most important ones, present in 50 to 75 percent of patients with IgM-associated neuropathies, are the ones that react with a MAG, related glycolipids, or sulfatide components of myelin (referred to as SGPG and SPLPG). Deep sensory loss with gait imbalance, severe tremor, and a Romberg sign are typical findings in the group with anti-MAG activity, while weakness and atrophy tend to appear later in the illness. Other IgM antineuronal antibodies have a more tentative connection to polyneuropathy. Polyclonal IgM antibodies against the GM1 antigen of myelin are linked with multifocal motor conduction block, described further on, but are sometimes found coincidentally in patients with anti-MAG protein. It is reasonable to assume that IgG monoclonal gammapathies are also capable of causing chronic neuropathies, but the evidence is less compelling and based mainly on the frequency of their coincidence. Indeed, it has been suggested that in many reported in-
stances this association is coincidental. Nonetheless, when such cases are treated similarly to the IgM group with neuropathy, they respond as well or better. Finally, it should be noted that in about 15 percent of our patients with anti-MAG antibody the illness has been mild and static for years at a time, even without treatment.

Only a small number of our patients have developed myeloma or Waldenstrom disease. A bone marrow examination is generally not necessary unless the concentration of the paraprotein exceeds 3 g/dL or climbs progressively over years, or if other hematologic changes such as unexplained anemia or thrombocytopenia develop.

Treatment In most cases of uncomplicated monoclonal gammopathy, particularly if not of long-standing, plasma exchange produces transient improvement for several weeks to months, somewhat more so in patients with IgG and IgA types of neuropathy than in those with the IgM type (Dyck et al, 1991). The treatment regimen is approximately the same as for GBS, a total volume of approximately 200 to 250 mL/kg exchanged in each of 4 to 6 treatments over about 10 days and the removed plasma replaced with a mixture of albumin and saline.

In patients who are found to have serum activity against specific components of myelin (particularly anti-MAG), plasma exchange alone has effected transient improvement in only 30 to 40 percent and sustained improvement in only 10 percent of our patients. This discouraging outcome was obtained in cases with slowly progressive ataxia and marked distal sensory loss. Sequential series of plasma exchanges every two to four months has sometimes resulted in repeated but transient responses. According to some reports the response to immunosuppression with intravenous cyclophosphamide or fludarabine, mycophenolate (Cellcept), or oral chlorambucil, when coupled with plasma exchanges has been somewhat better, at times allowing a reduction in the frequency of exchanges. We have observed this only with cyclophosphamide (Gorson et al). Rituximab, which has the appeal of having a preferential effect on the B-cell lymphocyte population, is being tested (Gorson et al). Rituximab, which has the appeal of having a preferential effect on the B-cell lymphocyte population, is being tested (Gorson et al). Rituximab, which has the appeal of having a preferential effect on the B-cell lymphocyte population, is being tested (Gorson et al). Rituximab, which has the appeal of having a preferential effect on the B-cell lymphocyte population, is being tested (Gorson et al). Rituximab, which has the appeal of having a preferential effect on the B-cell lymphocyte population, is being tested (Gorson et al).

Improvement with high-dose infused immunoglobulin (IVIG) has been effective in half of our cases with typical paraproteinemia, and 20 percent of those with anti-MAG neuropathy have improved for at least a brief period. Other reports are not as positive. In almost all instances immunosuppression and the plasma exchanges or IVIG must be repeated indefinitely at intervals of one to several months as determined by the clinical course. An indwelling catheter is then usually required for venous access. This group of neuropathies responds poorly or not at all to corticosteroids.

Osteosclerotic Myeloma (POEMS Syndrome) and Multiple Myeloma A neuropathy associated with multiple myeloma has already been mentioned under “Paraneoplastic Neuropathy and Sensory Ganglionopathy.” This polyneuropathy complicates 13 to 14 percent of cases of multiple myeloma and has a disproportionately high association with the osteosclerotic form of the disease. An abnormal monoclonal and excessive gamma globulin (mainly with the kappa light chain component in multiple myeloma but lambda in the osteosclerotic type) is found in the serum of over 80 percent of patients with myelomatous neuropathy.

A small and special group of patients with single or other limited degrees of osteosclerotic myeloma, a sensorimotor polyneuropathy termed POEMS arises. [Polyneuropathy (P) of moderate severity is associated with organomegaly (O), endocrinopathy (E), elevated M protein, and skin changes S (mainly hypertrichosis and skin thickening), hence the acronym POEMS]. The same process has been referred to as the Crow-Fukase syndrome in Japan, where the disease is prevalent. In many cases of POEMS there is lymphadenopathy attributable to the angiofollicular hyperplasia of Castleman disease. Another characteristic feature of the osteosclerotic-related polyneuropathy is a greatly elevated CSF protein. The presence of the disease can be suspected from the presence of an immunoglobulin spike in the blood, often polyclonal or bicalonal rather than monoclonal, and possessing a lambda light chain component. The diagnosis requires the demonstration of the osteosclerotic lesion by a radiographic survey of the long bones, pelvis, spine, and skull (a bone scan is often insensitive) and a bone marrow examination, which shows a moderate increase in the number of well-differentiated plasma cells. In most of our patients there have been several discrete bone lesions concentrated in the ribs and spine; the skull and long bones may harbor such lesions as well, or the lesions may be in the form of a single nodule, often in the spinal column.

Treatment The neuropathy that complicates a solitary plasmacytoma may improve markedly following irradiation of the bone lesion. Multiple lesions, including those in the POEMS syndrome, when treated with chemotherapy (melphalan and prednisone) or focused radiation, demonstrate some improvement or stabilization in the neuropathy. Treatment with plasma exchange has yielded uncertain but somewhat positive results in our patients.

Waldenstrom Macroglobulinemia Macroglobulinemia was the term applied by Waldenstrom to a systemic condition occurring mainly in elderly persons and characterized by fatigue, weakness, and a bleeding diathesis. Immunelectrophoretic examination of the blood disclosed a marked and mostly monoclonal increase in the IgM plasma fraction. About half of patients with Waldenstrom disease and polyneuropathy will have anti-MAG antibodies, similar to the proportion in patients with nonmalignant IgM paraproteins. A significant proportion of patients with this hyperproteinemia have a hyperviscosity state manifest by diffuse slowing of retinal and cerebral circulation—giving rise to episodic confusion, coma, impairment of vision, and sometimes strokes—(Bing-Neel syndrome). The neuropathy, when present, evolves over months or longer and may be asymmetrical, particularly at the onset, but becomes symmetrical and distal. The pattern in our patients has been of the latter type, very slowly progressive, and limited to the feet and legs with mild sensory ataxia and loss of knee and ankle jerks. The CSF protein is usually elevated and the globulin fraction increased. In a case recorded by Rowland and colleagues, the polyneuropathy was purely motor and simulated motor neuron disease; other cases of this type, albeit rare, have been brought to our attention in clinical exercises and medical writings. Treatment is discussed below.

Cryoglobulinemia As mentioned previously in the section on vasculitic neuropathies, cryoglobulin, a serum protein that precipitates on cooling, is usually of the IgG or IgM type and most often polyclonal. While cryoglobulinemia may occur without any apparent associated condition (essential cryoglobulinemia), it also accompanies a wide variety of disorders such as multiple myeloma, lymphoma, connective tissue disease, chronic infection, and, particularly, hepatitis C. Peripheral neuropathy occurs in a small proportion both of the essential and symptomatic cases. Occasionally the neuropathy evolves over a period of a few days and remits rapidly. More often it takes the form of a distal symmetrical sensorimotor loss, which develops insidiously in association with the Raynaud phenomenon and purpuric eruptions of the skin. Initially, the neuropathic symptoms consist only of pain and paresthesias that may be precipitated by exposure to cold (as often, there is no
cold sensitivity). Later, weakness and wasting develop, more in the legs than in the arms, and more or less in the distribution as the vascular changes. In some cases there may be a mononeuropathy multiplex with severe denervation in the territory of the involved nerves (García-Bragado et al). In a few cases, the two neuropathic syndromes have been combined.

As remarked earlier, detection of cryoglobulin requires special handling of the blood sample. The specimen should be carried to the laboratory in a bath of warm water to prevent precipitation of the protein.

Any of the paraproteinemic states may be associated with amyloid polyneuropathy. This subject is accorded a separate section later.

The pathology of the cryoglobulinemic and macroglobulinemic neuropathies has been incompletely studied and the mechanisms by which these disorders cause neuropathy are uncertain. One presumes that some component of the paraprotein acts as an antineural antibody or that deposition of the protein is in some way toxic. In our most thoroughly autopsied case, there was widespread distal axonal degeneration of nondescript type without amyloid deposition or inflammatory cells; yet in other reported cases, amyloid has been found in the nerve and the neuropathy has been attributed directly to it. Immune deposits of IgM had impregnated the inner layers of the perineurium in the case reported by Ongerboer de Visser and colleagues. Dalakas and Engel have made similar observations. In yet other instances, the neuropathy of cryoglobulinemia is due to the intravascular deposition of cryoglobulins, causing a more acute vasculitic mononeuritis multiplex as discussed earlier (Chad et al).

Treatment In the macro- and microglobulinemic neuropathies, the use of prednisone, the alkylating agent chlorambucil, cyclophosphamide, and repeated plasma exchange has at times led to improvement both in the systemic and neuropathic symptoms, although recovery has been incomplete. The optimal treatment of cryoglobulinemic neuropathy has not been settled. We have used plasma exchange and added immunosuppression in the vasculitic variety of this disease.

Primary (Nonfamilial, AL) Amyloid Neuropathy A heredofamilial type of amyloidosis is well known. There are in addition more numerous sporadic instances of a peripheral neuropathy caused by amyloid deposition. As in the familial variety, the heart, kidneys, and gastrointestinal tract may be involved. This acquired type of amyloid disease has also been called primary systemic amyloidosis to distinguish it from the variety associated with chronic diseases. In most cases, the amyloid is derived from a paraproteinemia for which reason it is included in this section, but the proportion of “benign” and malignant plasma cell sources of the protein varies from one report to another. For example, in the large series of Kyle and Bayrd, only 26 percent of patients with primary amyloidosis had a malignant plasma cell dyscrasia. This agrees with our own experience, but other series have found rates of myeloma as high as 75 percent. In either case, 90 percent of cases of primary amyloidosis are the result of a monoclonal protein in the blood (rarely polyclonal). Macrophage enzymes cleave the larger immunoglobulin molecules as light chains that aggregate to form amyloid deposits in tissue, or the plasma cells may produce light chains directly (“light chain disease”). Lambda light chain predominates in the idiopathic variety of amyloidosis, and kappa light chain is more common in myeloma. In a few cases the light chain is found only in the urine (as Bence Jones protein).

In primary amyloidosis there is no evidence of preceding or coexisting disease (except the association with paraproteinemia or multiple myeloma). Secondary amyloidosis, an infrequent occurrence nowadays, is the result of chronic infection or other chronic disease outside the nervous system and, as a rule is not associated with neuropathy. In contrast, familial amyloidosis, a third variety, is almost invariably associated with neuropathy but is associated with a paraprotein in a small proportion of cases and the amount of immunoglobulin is small (see page 1160).

Primary amyloidosis is mainly a disease of older men, the median age at the time of diagnosis being 65 years. In our clinical material, the majority of the patients have had peripheral neuropathy but this may reflect a referral bias since in other series less than one-third were so affected (Kyle and Dyck). The neuropathic symptoms and signs are similar to those of hereditary amyloid polyneuropathy discussed further on, but the progress of the disease is considerably more rapid.

The initial symptoms are sensory—numbness, paresthesias, and often acral pain—and the signs are characteristic of involvement of small-diameter sensory fibers (loss of pain and thermal sensation). It is the painful aspect and the autonomic features discussed later that distinguish this disease from the paraproteinemic neuropathies and indeed, from most other polyneuropathies. Weakness follows, initially limited to the feet but becoming more extensive as the disease progresses and eventually spreads to the hands and arms. There is only later a loss of mainly large fibers that mediate sensations of touch, pressure, and proprioception. Twenty-five percent of patients have carpal tunnel syndrome from infiltration of the flexor retinaculum. Exceptionally, patterns other than the painful and sensory predominant polyneuropathy have been associated with amyloidosis. Preferential involvement of motor nerves, lumbar roots, plexopathy, and amyloidomas involving single nerves (sciatic, facial, trigeminal) have been reported. Unusual cases of mononeuritis multiplex have been difficult to explain, including a reported case by Gorson and Skinner.

Autonomic involvement can be severe and may become evident early in the course of the illness; several of our patients presented with disturbances of gastrointestinal motility, especially episodic diarrhea and orthostatic symptoms or impotence and bladder disturbances. The pupils may show a slow reaction to light, or there may be a reduction in sweating. An infiltrative amyloid myopathy also occurs as a rare complication of the disease; it presents as an enlargement and induration of many muscles, particularly those of the tongue (macroGLOSSIA), pharynx, and larynx.

Progression of the illness is relatively rapid, the mean survival being 12 to 24 months. An indolent neuropathy that evolves over years is not likely to be due to amyloidosis, though we have seen such a case. Death is usually due to the renal, cardiac, or gastrointestinal effects of amyloid deposits, the manifestations of which are already evident in over half of the patients who present with neuropathy. A nephrotic syndrome is characteristic.

Analysis of the serum and urine, searching for an abnormal paraprotein is the most useful screening test. Next in value is a microscopic examination of abdominal fat pad, gingival, or rectal biopsy for deposition of amyloid in tissue or blood vessels. If a sensory neuropathy or evidence of organ infiltration is evident, biopsy of the sural nerve or of the involved viscera has a high diagnostic yield. Muscle tissue gives variable results. The liver biopsy is positive in virtually all cases and the kidney shows amyloid infiltration in 85 percent. In several of our patients with a clinical syndrome typical of amyloid neuropathy, but in whom amyloid was absent in the sural nerve, the diagnosis was established only after
sequential biopsy of numerous sites (fat pad, kidney, liver). Also, if the sural nerve is severely depopulated of nerve fibers, the amount of congophilic staining and the characteristic birefringence may be meager and yield a spuriously negative result. It is also critical to assure the accuracy of congophilic staining by comparison with positive and negative control tissue from the same laboratory. The CSF has a normal or mildly elevated protein concentration but this does not distinguish the neuropathic process from many others.

Lachmann and colleagues have emphasized that 10 percent of patients who appear by all the usual criteria to have primary amyloidosis will turn out in the end to have a genetic type. However, only a small proportion of the latter group has a monoclonal gamopathy and it tends to be of low concentration (estimated to occur in one quarter of familial cases but we have not encountered it). This difference and the rapid progression of the primary acquired form assist in distinguishing it from the genetic type.

In addition to the more slowly evolving familial types, the differential diagnosis of acquired amyloid neuropathy includes the myelomatous varieties, toxic and nutritional small-fiber neuropathies, paraneoplastic polyneuropathy, Sjögren disease, and an idiopathic small-fiber sensory neuropathy, all of which can cause pain either in a steadily progressive or stepwise manner, attaining its prognosis. As a rule, CIDP begins insidiously and evolves slowly, with cytoalbuminologic dissociation of the CSF (raised protein concentrations) and pathologically, both show similar multifocal perivascular inflammatory infiltrates. But there are also important differences in cases of long-standing. In the series reported by McCombe et al, 6 of 53 patients developed a cerebellar-like tremor (corresponding to the relapsing and stepwise progressive forms of CIDP), and in another third, and relapsing in the remaining third. The periods of worsening or improvement were measured in weeks or months. Infections and inoculations in the 3 months preceding the onset of CIDP were no more frequent than in the population at large. Weakness of the limbs, particularly of the proximal leg muscles, or numbness, paresthesias, and dysesthesias of the hands and feet were the initial symptoms. In 45 of the 53 patients, the signs were those of a mixed sensorimotor polyneuropathy with weakness of the shoulder, upper arm, and thigh muscles, in addition to motor and sensory loss in the distal parts of the limbs. In 5 patients the neuropathy was purely motor, and in 3, purely sensory. Cranial nerve abnormalities were distinctly unusual. Enlarged, firm nerves were found in 6 patients. Not emphasized in their series is the common occurrence of a cerebellar-like tremor in cases of long-standing. In the series reported by McCombe et al, comprising 92 patients, two major subgroups were recognized—relapsing (corresponding to the relapsing and stepwise progressive cases of Dyck et al) and nonrelapsing ones. In our own series of more than 100 patients, we have been impressed with several additional unusual patterns of clinical presentation. In 10 percent, numbness and weakness of the hands preceded involvement of the feet, which is unusual in other polyneuropathies. A sensory ataxic form, a purely motor form, and mononeuropathies superimposed on a mild generalized polyneuropathy each accounted for approximately 5 percent of the cases. As mentioned earlier, a small pro-

Chronic Inflammatory Demyelinating Polyradiculoneuropathy
This form of polyneuropathy was separated from acute inflammatory polyradiculopathy, or GBS, by Austin in 1958 on the basis of a prolonged and relapsing course, enlargement of nerves, and responsiveness to corticosteroids. Excluding the duration of evolution, there are numerous clinical similarities between the acute and chronic forms. Both are widespread polyradiculoneuropathies, usually with cytoalbuminologic dissociation of the CSF (raised protein concentration with fewer or no cells); both exhibit nerve conduction abnormalities characteristic of a demyelinating neuropathy (reduced conduction velocity and partial conduction block in motor nerves), and pathologically, both show similar multifocal perivenous inflammatory infiltrates. But there are also important differences, the most evident of which are the mode of evolution and prognosis. As a rule, CIDP begins insidiously and evolves slowly, either in a steadily progressive or stepwise manner, retaining its maximum severity after several months or longer. From the beginning it may be asymmetrical or involve the arms predominantly. However, in a small proportion of patients (16 percent in the series of McCombe et al, and a smaller proportion in our own series) the disease at first emerges from a mild or moderate case of GBS. In these latter cases the illness thereafter becomes relapsing or it simply worsens slowly and progressively.

An antecedent infection is identified far less regularly in patients with CIDP than in those with GBS and is probably not a necessary component of the disease. Furthermore, CIDP may be distinct immunologically from GBS, insofar as certain HLA antigens occur with greater frequency in patients with CIDP than they do in the normal population, whereas there are no clear HLA predispositions in patients with GBS. Finally, in contrast to acute GBS, many cases of CIDP respond favorably to the administration of prednisone. An ambiguity is introduced here because, as mentioned earlier, Hughes has described a group of patients with polyneuropathies in whom weakness progressed steadily for 4 to 12 weeks and who responded to corticosteroids, thus again blurring the distinction between GBS and CIDP.

The chronic symmetric sensorimotor loss coupled with EMG findings of demyelination largely define the illness. The typical EMG findings are of multifocal conduction block as described in Chap. 45, prolonged distal latencies (distal block), nerve conduction slowing to less than 80 percent of normal in several nerves, loss of late responses, and dispersion of the compound muscle action potentials, further reflecting demyelination in motor nerves. One or several of these changes have been present in more than three quarters of our patients (Gorson, Ropper, et al). In the early stages of the disease demyelinating features must be carefully sought by testing multiple nerves at several sites along this course. After several months there is often some degree of axonal change (30 percent of our series), but the fundamental process continues to be one of multiple foci of demyelination. Most dependable is the absence of denervation changes early on despite weakness and reduced amplitude of the motor action potential, indicative of a demyelinating block to conduction at a proximal site.

Several large series of CIDP cases are available for review. Dyck and colleagues (1975) studied 53 patients in whom the neuropathy progressed for more than 6 months. The clinical course was monophasic and slowly progressive in about one-third, stepwise and progressive in another third, and relapsing in the remaining third. The periods of worsening or improvement were measured in weeks or months. Infections and inoculations in the 3 months preceding the onset of CIDP were no more frequent than in the population at large. Weakness of the limbs, particularly of the proximal leg muscles, or numbness, paresthesias, and dysesthesias of the hands and feet were the initial symptoms. In 45 of the 53 patients, the signs were those of a mixed sensorimotor polyneuropathy with weakness of the shoulder, upper arm, and thigh muscles, in addition to motor and sensory loss in the distal parts of the limbs. In 5 patients the neuropathy was purely motor, and in 3, purely sensory. Cranial nerve abnormalities were distinctly unusual. Enlarged, firm nerves were found in 6 patients. Not emphasized in their series is the common occurrence of a cerebellar-like tremor in cases of long-standing. In the series reported by McCombe et al, comprising 92 patients, two major subgroups were recognized—relapsing (corresponding to the relapsing and stepwise progressive cases of Dyck et al) and nonrelapsing ones. In our own series of more than 100 patients, we have been impressed with several additional unusual patterns of clinical presentation. In 10 percent, numbness and weakness of the hands preceded involvement of the feet, which is unusual in other polyneuropathies. A sensory ataxic form, a purely motor form, and mononeuropathies superimposed on a mild generalized polyneuropathy each accounted for approximately 5 percent of the cases. As mentioned earlier, a small pro-
portion began as acute GBS but continued to progress or relapsed in the following months (Gorson et al, 1997). Other comprehensive accounts have been given by Barohn, Comblath, Dyck, and Hughes and their associates. All of these studies delimited the time course of CIDP to encompass progression for longer than 8 or 12 weeks. The term subacute demyelinating neuropathy has been used to describe a Guillain-Barré illness that progresses for only 4 to 8 weeks and is responsive to corticosteroids.

Also recognized is the frequency (up to one quarter of the patients in some series, less often in our experience) with which there was a systemic condition such as paraproteinemia, lymphoma, an undifferentiated reactive adenopathy, or lupus in association with an inflammatory demyelinating polynueropathy. These associations create problems in nosology that can be reconciled by labeling a given instance as “CIDP with paraproteinemia,” “CIDP with lupus,” etc., thus separating such cases from the idiopathic variety. These symptomatic inflammatory polynueropathies respond to corticosteroids, albeit unpredictably, and to treatment of the underlying disease.

The status of a predominantly axonal polynueropathy that clinically simulates CIDP and responds to some extent to the same immunomodulating treatments has been described by Uncini et al and by Gorson and Ropper. The present authors have the impression that it is an immune-mediated neuropathy comparable to CIDP but obviously with preferential destruction of axons rather than of myelin. Its frequency as a cause of acquired polynueropathy is not known but we see several new cases every year.

**Laboratory Features** The CSF protein is elevated in 80 percent of patients with CIDP, typically in the range of 75 to 200 mg/dL. In rare instances there is papilledema and a pseudotumor syndrome in relation to extremely high levels of CSF protein (usually >1000 mg/dL). Elevation of the CSF gamma globulin fraction and a mild lymphocytic pleocytosis are reportedly found in 10 percent of patients (more consistently in those that are HIV-seropositive), a considerably higher percentage than in our series.

In biopsy material (sural nerve), half of cases are found to have interstitial and perivascular infiltrates of inflammatory cells, although one expects that most nerves would show these changes if a sufficient number could be sampled. In other biopsy specimens there is only demyelination, or in cases of long-standing, severe depletion of all nerve fibers. As in GBS, the demyelination appears to be effected by T cells and macrophages within the endoneurium and perineurium. The loss of myelinated fibers is variable and many of the remaining fibers are seen to be undergoing wallerian degeneration or show changes of segmental demyelination or demyelination-remyelination. So-called onion-bulb formations are conspicuous in the recurrent and relapsing cases. The few complete autopsy studies have shown only minimal or patchy inflammation and a considerable degree of axonal damage, probably reflecting the long duration of illness before examination. The presence of endoneurial and subperineurial edema has been emphasized by Pri-neas and McLeod.

**Treatment** Several well-conducted trials have shown that there is short-term benefit from the intravenous infusion of high doses of gamma globulin (2 g/kg in divided infusions over 4 or 5 days). More than half of our patients have responded to this treatment, albeit for only several weeks or months, after which the infusions must be repeated. A desire to spare patients the side effects of indefinite prednisone administration (see later) make this mode of therapy a reasonable alternative. Some patients have been treated with repeated infusions for almost 10 years without ill effects. Patients who require treatment at such short intervals as to be impractical have benefited from the addition of small doses of prednisone or of an immunosuppressive drug as described below. The main drawbacks of IVIG are its expense and the several hours required for its infusion. Rare instances of nephrotic syndrome, aseptic meningitis, serum sickness, thrombolic arterial occlusion, including stroke and hypotension have been reported, particularly if the infusion is too rapid.

Half of patients with CIDP also respond well to plasma exchanges. In a prospective double-blind trial, Dyck and colleagues found that plasma exchange administered twice weekly for 3 weeks had a beneficial effect on both neurologic disability and nerve conduction. The response to plasma exchange in our patients has been comparable to that obtained with IVIG and with steroids, but it has become clear that some patients respond to one type of treatment and not the other. The beneficial effects in most patients begin to subside in 10 to 21 days, or even less. In some cases the response lasts longer, as found by Dyck and in the series by Hahn et al. For these reasons we prefer to try plasma exchange or immune globulin before committing a patient to long-term treatment with predniso- one. The relative ease of administering IVIG favors its use first, followed by a series of plasma exchanges if there is no improve- ment. When there is a clear response, three or four brief series of plasma exchanges or repeated infusions of immune globulin often suffice to bring the patient to an improved level of function. These treatments can be supplemented by small doses of prednisone when frequent infusions or exchanges become impractical.

It has been our experience that in about one-third of cases, IVIG and plasma exchange may cease to have clinical benefit after repeated use for one or more years. Corticosteroids were formerly the mainstay of therapy, but most patients become dependent on the medication and correspondingly suffer side effects. The general approach has shifted to utilizing these medications as a third type of treatment after plasma exchange or IVIG, and as an adjunct to one of the previously mentioned treatments. The usual regimen begins with 60 to 80 mg of prednisone daily that is tapered over months to the lowest effective dose, typically 25 to 40 mg. A small number of patients will have no response to corticosteroids within the first 1 or 2 months but will do so if treatment is continued. The drug produces tremor or may exaggerate the tremor caused by the neuropathy. Should a sustained trial of prednisone therapy prove unsuccessful, a course of azathioprine (for at least 3 months), 3 mg/kg in a single daily dose, has been recommended (Dalakas and Engel), but as mentioned, a controlled trial has failed to show benefit from this combination and we have had little success with it.

When the preceding measures prove unsatisfactory, cyclo- phosphamide or mycophenolate can be added, or another similar immunosuppressive medication, but we have been unable to draw any firm conclusions as to the effectiveness of these combined regimens.

Some patients who have failed to benefit from the aforementioned treatments have improved in response to the administration of α-interferon (Gorson et al), and Vallat has shown in a small trial that β-interferon may be similarly successful in a small group of patients who failed other therapies. A larger trial is being conducted in order to determine if adjunctive treatment with β-interferon al- lows an increase in the interval between infusions of IVIG. High- dose cyclophosphamide has proven helpful in several cases under our care, although it has as often failed (see Brannagan et al). The usual regimen is 50 mg/kg IV daily for 4 days followed by gran- ulocyte-stimulating factor beginning on the tenth day until the ab-
solute neutrophil count recovers. Individual reports of successful treatment by autologous stem-cell transplantation after high-dose chemotherapy have appeared (Vermuelen and van Oers). This may become an option in severe and treatment-resistant cases. We have no explanation for the remarkable improvement and continued good health of a few of our patients after a severe toxic bacterial infection (Ropper).

One of the problems most difficult to address is a lack of clear clinical measurements to guide retreatment with IVIG and plasma exchange and even the proper adjustment of the steroid dose. Often one may be influenced by the patient’s fear of losing any ground and even slight changes in sensory or motor symptoms.

It has been stated that patients with discrete relapses have a better prognosis than those with a progressive course. In McCombe’s series, 73 percent were said to have eventually recovered but the long-term outcome has generally been poor. In a small number of patients, less than 10 percent, has the disease finally burned out. Unexplained remission occurs occasionally.

Multifocal Motor Neuropathy and Multifocal Conduction Block Several polyneuropathies that share many of the features of CIDP have been delineated on the basis of some unique clinical or electrophysiologic attribute. These include particularly multifocal motor neuropathy and multifocal conduction block. The latter seems to be a type of CIDP with the main feature being a block to sensory and motor conduction across focal sites in a limited number of nerves as described below. In multifocal motor neuropathy, there are multiple sites of block in motor nerves alone, without change in sensory conduction.

The distinction between these two entities has been somewhat blurred by the finding of mild but consistent demyelination in sensory nerve biopsies from patients with multifocal motor neuropathy (Corse et al). While these conditions may perhaps be considered sory nervebiopsies from patients with multifocal motor neuropathy blurred by the finding of mild but consistent demyelination in sen-

sory and motor conduction across focal sites in a limited number of patients, less than 10 percent, has the disease finally burned out. Unexplained remission occurs occasionally.

Multifocal Motor Neuropathy and Multifocal Conduction Block Several polyneuropathies that share many of the features of CIDP have been delineated on the basis of some unique clinical or electrophysiologic attribute. These include particularly multifocal motor neuropathy and multifocal conduction block. The latter seems to be a type of CIDP with the main feature being a block to sensory and motor conduction across focal sites in a limited number of nerves as described below. In multifocal motor neuropathy, there are multiple sites of block in motor nerves alone, without change in sensory conduction.

The distinction between these two entities has been somewhat blurred by the finding of mild but consistent demyelination in sensory nerve biopsies from patients with multifocal motor neuropathy (Corse et al). While these conditions may perhaps be considered for the moment as types of CIDP, there is a high concordance of multifocal motor neuropathy with a particular IgM antibody, anti-GM1, directed against a ganglioside component of peripheral myelin (Pestronk et al). For this reason, some view this illness as belonging to the class of paraproteinemic neuropathies (see earlier and Simmons et al), and it is distinctive enough clinically to be categorized separately. Its importance as a clinical entity lies in the similarity of the clinical picture to a purely lower motor neuron type of amyotrophic lateral sclerosis and, unlike ALS, its responsiveness to treatment.

Multifocal motor neuropathy predominates in men. It usually begins with an acute to subacute motor mononeuropathy, manifest, for example, as weakness of the wrist or foot drop, and is often joined insidiously by another focal motor palsy. The process is painless, unlike vasculitic mononeuritis multiplex, involves the nerve incompletely, and, in its usual form, is unaccompanied by any sensory symptoms such as paresthesias or numbness. Despite the initially demyelinating character of the disorder, there is almost always atrophy of the weakened muscle within months, and there may be a few fasciculations, thus reminiscent of ALS. Nevertheless, the weakness tends to be out of proportion to atrophy. Usually, the tendon reflex is lost or muted in an affected region, but for unexplained reasons, some patients have one or more brisk reflexes. Our experience has been that this latter reflex change does not reach the point of appearing “pathologic” and that clonus and Babinski signs are categorically not part of the illness.

When there is an association with sensory symptoms or sensory loss and there is slowing of sensory conduction in regions of motor conduction block, the acronym MADSAM (Multifocal Acquired Demyelinating Sensory and Motor Neuropathy) has been used, but the disorder while similar to multifocal conduction block, more resembles CIDP. This also conforms to what has been called Lewin-Sumner syndrome based on the original description by these authors and their colleagues of subacute, painless asymmetric, distal multiple mononeuropathies. The ulnar and median nerves were involved and there was motor conduction block and sensory slowing in affected nerves. Curiously, two of their five original patients had optic neuritis, a feature not reported by others. The disease is not connected to antibodies against GM1.

Treatment For multifocal motor conduction block, IVIG infusions have been highly effective, albeit temporarily, in over half of patients. Some authoritative clinicians favor the early addition of cyclophosphamide, 1 g/m² monthly for 6 months in treatment-resistant cases or when the frequency of infusions is unsustainable. Other immune-modulating drugs such as rituximab are being tried. There is no response to corticosteroids. The MADSAM illness responds similarly to CIDP in most instances.

Uremic Polyneuropathy Polyneuropathy is among the most common complications of chronic renal failure. Robson estimated that it complicates end-stage renal failure in two-thirds of patients who are about to begin dialysis therapy. Bolton’s figures are much the same; 70 percent of his patients being dialyzed regularly had uremic polyneuropathy and in 30 percent it was moderate or severe in degree. As in the original description by Asbury, Victor, and Adams, the neuropathy takes the form of a painless, progressive, symmetrical sensorimotor paralysis of the legs and then of the arms. In some patients, the neuropathy begins with burning dysesthesias of the feet or with sensations of creeping, crawling, and itching of the legs and thighs, which tend to be worse at night and are relieved by movement (“restless legs” syndrome, page 339). Renal failure accompanied by diabetes may give rise to a particularly severe form.

The combination of muscle weakness and atrophy, areflexia, sensory loss, and the graduated distally predominant distribution of the neurologic deficit in the limbs leaves little doubt about the neuropathic nature of the disorder. Usually the neuropathy evolves slowly over many months, at times more subacutely. Infrequent instances of a more acute sensorimotor polyneuropathy that have been reported occur mainly in diabetic patients receiving peritoneal dialysis as discussed earlier on (see page 1128; Ropper; Asbury et al.). Also, a rare uremic polymyositis with hypophosphatemia has been described (Layzer). The neuropathy has been observed with all types of chronic kidney disease. More important to the development of chronic neuropathy than the nature of the renal lesion are the duration and severity of the renal failure and symptomatic uremia.

With long-term hemodialysis, the neuropathic symptoms and signs stabilize but improve in relatively few patients. In fact, rapid hemodialysis may occasionally worsen the polyneuropathy temporarily. Peritoneal dialysis appears to be more successful than hemodialysis in improving the neuropathy but this observation has not been firmly established. Complete recovery, occurring over a period of 6 to 12 months, usually follows successful renal transplantation for the reasons given later.

The pathologic findings are those of a nonspecific axonal degeneration. In rapidly progressive cases, there is a tendency for the large fibers to be affected; this is evident particularly on electrophysiologic testing which shows slowing of nerve conduction ve-
Figure 46-4. Patterns of sensory loss in leprosy. The localization of these areas to cooler portions of the body is unique to this disorder. Shown in the upper figure is the sparing of the palmar and antecubital surfaces and variation in the sensation within the distribution of a single sensory nerve. In the lower figure, almost universal analgesia is found but there is still sparing of warmer regions of skin. (From Sabin with permission.)

Locities, but there is no conduction block as occurs in other acquired demyelinating polyneuropathies. The pathologic changes are most intense in the distal segments of the nerves, with the expected chromatolysis of their cell bodies.

The cause of uremic polyneuropathy is unknown. What has been called the “middle molecule” theory is plausible. The end stage of renal failure is associated with the accumulation of toxic substances in the range of 300 to 2000 molecular weight. Furthermore, the concentration of these substances, which include methylguanidine and myoinositol, has been shown to correlate with the degree of neurotoxicity (Funck-Brentano et al). These toxins (and the clinical signs of neuropathy) are not greatly reduced by chronic hemodialysis. In contrast, the transplanted kidney effectively eliminates substances of wide-ranging molecular weights, which would account for the almost invariable improvement of neuropathy after transplantation. As is the case with uremic encephalopathy, urea alone given to experimental animals and in controlled studies of humans, does not seem capable of inducing a metabolic neuropathy.

Alcoholic-Nutritional Polyneuropathy (See page 989 and Chap. 41) In all patients with alcoholic-nutritional polyneuropathy who for some reason remain untreated with vitamin and protein restoration, the weakness and atrophy of the legs, and to a lesser extent the arms, may reach an extreme degree. Thus this disease, though subacute in its evolution as described earlier in the chapter, becomes a frequent cause of chronic polyneuropathy. There are usually prominent sensory features and considerable acral pain and allodynia. Certain cases of diabetic neuropathy behave similarly.

Leprous Polyneuritis This is the classic example of an infectious neuritis, due to the direct invasion of nerves by the acid-fast Mycobacterium leprae. The disease is still frequent in India and Central Africa, but there are many lesser endemic foci including parts of South America and of Florida, Texas, and Louisiana that border on the Gulf of Mexico.

The initial lesion in leprosy is an innocuous-appearing skin macule or papule, which is often hypopigmented and lacking in sensation and is caused by the invasion of cutaneous nerves by M. leprae. In patients with a degree of immunologic resistance to infection the disease may progress no further than this stage, which is spoken of as indeterminate leprosy, or it may evolve in several ways, depending mainly upon the resistance of the host. The bacilli may be locally invasive, producing a circumscribed epithelioid granuloma that involves cutaneous and subcutaneous nerves and results in a characteristic hypopigmented patch of superficial numbness and sensory loss (tuberculoid leprosy). The underlying subcutaneous sensory nerves may be palpably enlarged. If a large nerve in the vicinity of the granuloma is invaded (the ulnar, median, peroneal, posterior auricular, and facial nerves are most frequently affected), a sensorimotor deficit in the distribution of that nerve is added to the patch of cutaneous anesthesia.

In contrast to the limited tuberculoid variety of leprosy, lack of resistance to the organism permits the proliferation and hematogenous spread of bacilli and the diffuse infiltration of skin, ciliary bodies, testes, lymph nodes, and nerves (lepromatous leprosy). Widespread invasion of the cutaneous nerves produces a symmetrical pattern of pain and temperature loss involving the pinnae of the ears as well as the dorsal surfaces of hands, forearms, and feet and anterolateral aspects of the legs—a distribution that is determined by the relative coolness of these parts of the skin. This temperature-dependent pattern is the most characteristic feature of the disease as pointed out by our colleague T. Sabin. The sensory maps he has drawn (Fig. 46-4) are typical of established cases. The nose, earlobes, and elbows may be affected early as a result of the coolness of the skin in those areas. The process evolves over years. Eventually the anesthesia spreads to involve most of the cutaneous surface. Extensive sensory loss is followed by impaired motor function owing to invasion of muscular nerves where they lie closest to the skin (the ulnar nerve is the most vulnerable). There is a loss
of sweating in areas of sensory loss, but otherwise the autonomic nervous system is unaffected. In distinction to other polyneuropathies, tendon reflexes are usually preserved in leprosy despite widespread sensory loss. Probably this is the result of sparing of most of the muscular and larger sensory nerves. Because of widespread anesthesia, injuries may pass unrecognized, with resultant infections, trophic changes, and loss of tissue. Variations in host immunity result in patterns of disease having both tuberculoid and lepromatous characteristics (dimorphous leprosy). Erythema nodosum occurs in a few cases. The diagnosis can be made from a skin scraping or biopsy but often, multiple samples are required.

**Treatment** All forms of leprosy require long-term treatment with sulphones (dapsone being the most commonly used), rifampin, and clofazimine. The skin lesions of lepromatous leprosy are responsive to thalidomide, which itself may cause a sensory neuropathy (page 1041; Barnhill and McDougall). Reactivation of disease, or a conversion from the tuberculoid to the lepromatous pattern, may occur during times of reduced immunity.

**Polyneuropathy with Hypothyroidism** Although characteristic disturbances of skeletal muscle are known to complicate hypothyroidism (see Chap. 51), the demonstration of a definite polyneuropathy has been infrequent. However, a number of elderly myxedematous patients complain of weakness and numbness of the feet, legs, and, to a lesser extent, hands, for which no other explanation can be found. Loss of reflexes, diminution in vibratory, joint-position, and touch-pressure sensations, and weakness in the distal parts of the limbs are the usual findings. The neuropathic manifestations are seldom severe. Nerve conduction velocities are slowed, and the protein content of the CSF is usually increased to more than 100 mg/dl. Possibly the latter finding is a reflection of the increased protein content of the serum in the hypothyroid state. The subjective improvement and complete or near-complete reversibility of neuropathic signs following treatment with thyroid hormones provides convincing evidence of a hypothyroid etiology. In biopsies of nerve, an edematous protein infiltration of the endoneurium and perineurium, a kind of metachromatic mucoid material, has been seen. Dyck and Lambert (who should be credited for drawing attention to this neuropathy) noted segmental demyelination in teased fiber preparations. In electron-microscopic sections, a slight increase in glycogen, acid mucopolysaccharides, and aggregates of glycogen and cytoplasmic laminar bodies in Schwann cells have been observed by others.

Polyneuropathy of sensorimotor type has also been observed in association with a syndrome of chronic lymphocytic thyroiditis and alopecia (Hart et al).

**Chronic Mild Sensory Polyneuropathy of the Elderly (Burning Feet Syndrome)** All neurologists have observed numerous cases of a relatively nonprogressive sensory polyneuropathy in elderly patients. Tingling paresthesias of feet and lower legs, sensory loss, and absent ankle reflexes are the usual findings. The hands may be mildly affected but leg weakness and imbalance are absent or trifling. A painful variety is also known (see later). Laboratory studies may be normal or reveal minimally altered sensory conduction, but the evaluation has often not been extensive, and therefore it is difficult to say if Sjögren syndrome, glucose intolerance, or another underlying disease is responsible. Usually this chronic condition progresses little.

The most common variant of this form of chronic sensory polyneuropathy is one that affects mainly elderly women, who complain of slowly progressive (over years) painful burning and numbness of the feet, ascending to the ankles or midcalves. There are few findings on examination; often only a mild or moderate loss of pinprick and thermal sensation, and ankle reflexes that may or may not be reduced. Again, there is little or no progression over the years. Most of these cases are idiopathic but there is a broad differential diagnosis including the diseases mentioned earlier, as outlined by Mendell and Sahenk (Table 46-5 is adapted from their discussion). Identifiable causes for painful sensory neuropathy in elderly include mainly diabetes, alcoholic-nutritional deficiency states, connective tissue disease, amyloidosis, and vasculitis.

Electrophysiologic tests are likewise normal or virtually so; a few show diminished sural nerve potentials and minor changes of motor amplitudes. When these changes cannot be ascribed to diabetes, malnutrition, medications, or the other causes listed in the table, a substantial group of patients is left and are in need of symptomatic relief. Some have been helped by gabapentin or by antidepressants (amitriptyline, desipramine, or sertraline) and analgesic cream applied nightly to the soles and toes. Surprisingly, a few of the more severe cases have apparently responded to gamma globulin infusions but these observations require corroboration (Gorson and Ropper, 1995). In a number of cases of burning feet, the intradermal sensory nerves in skin biopsy specimens are said to be depleted of fibers but the meaning of this finding is not certain (Periquet et al).

**Multiple Symmetrical Lipomas with Sensorimotor Polyneuropathy** Whereas the usual cutaneous lipomas have no neurologic accompaniments, this clinical curiosity, known as Lannois-Bensaude disease, consists of symmetrical lipomas of the neck and shoulders that are associated with polyneuropathy and sometimes deafness. A mitochondrial disorder is suspected. Details can be found in the review by Neumann.

**GENETIC FORMS OF CHRONIC POLYNEUROPATHY**

In this large category of chronic polyneuropathy, symptoms evolve gradually over a period of many years. A polyneuropathy that advances slowly over a period of five to ten years or more is almost
invariably genetic in origin. The neuropathic disease may be remarkably restricted, as in familial analgesia with foot ulcers, or extensive, as in familial peroneal muscular atrophy. The time of onset of these very chronic neuropathies is usually in early life but often cannot be dated with certainty by the patient or family. In infants, the condition may be mistaken for muscular dystrophy or infantile muscular atrophy until sensory testing becomes possible. In the developing child, whose musculature naturally increases in power and volume with age, it may be difficult to decide whether the disease is progressive. In some cases, ataxia of the limbs may be pronounced at a stage when sensory loss exceeds paresis.

Strongly indicative of one of these conditions of early onset are pes cavus, hammer toes, and, in extreme forms, talipes equinus. One of these deformities is commonly detected in most cases of generalized inherited polyneuropathy. In later stages, trophic changes of skin and bone in distal parts of the limbs indicate involvement of small (pain) fibers, and the presence of deformed and degenerated joints (Charcot joint) appear and are indicative of a loss of articular pain fibers. The mutulating effects are the result of repeated injury to analgesic parts and to a lack of autonomic vascular reflexes. The atrophy of muscle and trophic changes in the skin are generally more marked than in the acquired forms of polyneuropathy.

The CSF protein content may remain mildly or moderately elevated over a period of years. Charcot-Marie-Tooth disease (type 1) shows slowed nerve conduction as a consequence of a disorder of myelin. A distinctive feature of hereditary neuropathy is the uniformity of the electrophysiologic changes, e.g., the same degree of slowing of nerve conduction velocity in all the nerves of the lower limbs, or in all the motor nerves, a feature that distinguishes this group from all acquired neuropathies.

There has been much difficulty in classifying the chronic familial polyneuropathies. Recent genetic findings have greatly simplified the matter of classification and have permitted the creation of a nosology that more or less parallels the clinical one. The proposed classifications in Tables 46-2 and 46-6 represent an attempt to conciliate the clinical and genetic data.

Of this large and varied group, only the sensorimotor Charcot-Marie-Tooth type is likely to be seen with any regularity by neurologists and general physicians. This group has become quite large as more individual mutations are discovered. The commonly encountered varieties are indicated in italics in Table 46-6. As a rough guide to the frequency of various types detected in a large neuromuscular clinic, Boerkoel and colleagues found that of 153 unrelated patients, 79 had the mutation that corresponds to the common variety of Charcot-Marie-Tooth disease (CMT1A), but what is of equal interest, 50 patients with a clear history of heredofamilial polyneuropathy had none of the currently detectable mutations.

Table 46-6 summarizes the major forms of hereditary neuropathy. These are designated as subcategories of Charcot-Marie-Tooth (CMT) disease and grouped by patterns of inheritance. Thus, the dominantly inherited myelinopathies have been designated CMT1 and the dominant axonopathies CMT2. The myelinopathies with onset in infancy are subsumed under CMT3, while most recessively inherited neuropathies (both axonal and demyelinating) are called CMT4. The hereditary sensory neuropathies, sometimes also called hereditary sensory and autonomic neuropathies, are also listed (HSN and HSAN). An alternate nomenclature, which describes the CMT classes as hereditary motor and sensory neuropathies (HMSN), is used elsewhere and mentioned in some of the discussion that follows.

Inherited Polyneuropathies of Mixed Sensorimotor-Autonomic Types

Peroneal Muscular Atrophy [Charcot-Marie-Tooth Disease, or CMT Types 1 and 2; Hereditary Motor-Sensory Neuropathy, or HMSN Types I and II (Dyck); and Related Conditions (See Table 46-6)] The hallmarks of this class of polyneuropathies are genetic transmission, complete symmetry, slow progression, and loss of myelin out of proportion to axons. These are the most common forms of inherited peripheral neuropathy and indeed among the most common of all inherited neurologic diseases. The frequency of the disease cannot be stated with precision because of its clinical heterogeneity, but the usually quoted prevalence is 1 in 2500 of the population, the most frequent subtype occurring in 1 in 4000. More than 15 subtypes have been described but only a few occur with any regularity.

Because the disease was described in 1886 almost simultaneously by Tooth in England and by Charcot and Marie in France, all their names have been attached to it, even though similar cases had been recorded earlier by Eulenberg (1856), Friedreich (1873), Ormerod (1884), and Osler (1880). The secondary changes in the spinal cord and the occasional association of this disease with Friedreich ataxia led early observers to consider it as a hereditary myelopathy and not to class it with the neuropathies, but the evidence supporting the latter grouping is now unassailable. The two important advances in our understanding of this disease since the original descriptions have been the separation of the main subtypes on the basis of their electrophysiologic (EMG) features, and the discovery of gene mutations which cause many of these diseases. In most cases, these mutations can be related to alterations in components of peripheral nerve myelin or axons.

Genetic Transmission The pattern of inheritance of Charcot-Marie-Tooth disease is most often that of an autosomal dominant trait, with almost complete penetrance; less often it is autosomal recessive and rarely X-linked dominant or X-linked recessive (see Table 46-6). Some cases, probably a small number, arise as de novo mutations (Hoogendijk et al). The common types that are connected to chromosomes 1 or 17 cannot be easily distinguished from one another on clinical grounds but they have distinctive EMG features. Seventy percent of CMT type 1 cases result from duplication of the gene for a peripheral myelin protein (PMP22) on chromosome 17 p11 (type CMT1A). Other studies of the PMP22 and PO (another myelin protein) gene expression in CMT1 and CMT3 cases (Dejerine-Sottas disease) have yielded discordant results because mutations on different loci, including one on chromosome 1, lead to different presentations, as noted in Table 46-6. The disease termed hereditary liability to pressure palsies also displays an aberration on chromosome 17, but in the form of a deletion rather than a duplication of the gene for PMP22. This disease is discussed further on, under “Brachial Plexus Neuropathies.” Yet another X-linked variant is the result of a mutation of the gene for connexin-32, another component of myelin, and is seen reasonably often.

Undoubtedly, further studies of genes and gene products will continue to advance our understanding of the inherited neuropathies, but for the present, clinicians are still best served by the descriptive clinical classification outlined in Table 46-2—acknowledging, of course, the clinical heterogeneity of this class of disorders.

Clinical and Electrophysiologic Features Dyck and Lambert and Harding and Thomas have subdivided CMT disease into two

### V. Miscellaneous Inherited Neuropathies

1. Giant axonal neuropathy (AR)
   - **PATHOLOGY:** axonal
   - **ONSET:** a
   - **GENE:** Gigaxonin
   - **FEATURES:** May respond to hematin, glucose

2. Porphyria (AR)
   - **PATHOLOGY:** axonal
   - **ONSET:** a
   - **GENE:** Porphobilinogen deaminase
   - **FEATURES:** May respond to hematin, glucose

3. “Mitochondrial” neuropathies
   - **PATHOLOGY:** axonal
   - **ONSET:** a
   - **GENE:** Myelin transcription factor SOX10
   - **FEATURES:** CNS, PNS hypomyelination

4. Severe PNS, CNS demyelination (AD)
   - **PATHOLOGY:** demyelinating
   - **ONSET:** inf, c

*The more common varieties of inherited neuropathy are italicized.
inf = infantile onset.
c = childhood onset.
a = adult onset.

The chronic degeneration of peripheral nerves and roots results in distal muscle atrophy beginning in the feet and legs and later involving the hands. The extensor hallucis and digitorun longus, the perone, and the intrinsic muscles of the feet are affected early in life and this muscle imbalance produces the bony changes of pes cavus and pied en griffe (high arches and hammertoes). Later, all muscles of the legs and sometimes the lower third of the thigh become weak and atrophic. The thin legs have been likened to those of a stork or, if the lower thigh muscles are affected, to an “inverted champagne bottle.” Eventually the nerves to the calf muscles degenerate and the ability to plantar flex the feet is lost. After a period of years, atrophy of the hand and forearm muscles develops. The hands later become clawed. The wasting seldom extends above the elbows or above the middle third of the thighs. Paresthesias and cramps are present, but only to slight or moderate degree and there is always some impairment, usually slight, of deep and superficial sensation in the feet and hands, shading off proximally. Rarely, the sensory loss is severe, and perforating ulcers may appear as in the pure sensory varieties of inherited neuropathy. The tendon reflexes are absent in the involved limbs. The illness progresses very slowly over decades, giving the impression of stabilization for long periods.

Walking difficulty, which is ultimately the main disability, is due to a combination of sensory ataxia and weakness. Foot drop and instability of the ankles are additional handicaps. The feet and legs may ache after use and cramps may be troublesome, as mentioned, but otherwise pain is unusual; the feet may become cold, swollen, and blue, secondary to inactivity of the muscles of the feet and legs and their dependent position. There is usually no disturbance of autonomic function. Fixed pupils, optic atrophy, nystagmus and endocrinopathies, epilepsy, and spina bifida, which have been reported
occasionally in association with peroneal muscular atrophy, probably represent coincidental congenital disorders. The only distinguishing clinical feature between types 1 and 2, and this is present in only a minority of cases, is enlargement of the nerves in type 1, most easily appreciated by palpation of the greater auricular nerves. Aside from secondary changes in bone formation such as pes cavus, these patients do not display dysmorphic features.

The clinical heterogeneity of CMT disease has been alluded to in the previous discussion and is evident in the numerous mutations that give rise to similar clinical polyneuropathies. Restricted forms are known to affect only the peroneal and pectoral or scapular muscles (scapuloperoneal form of Dawidenkow). The “familial claw foot with absent tendon jerks” of Symonds and Shaw is another similar variant.

Laboratory data are of little help, except for reduced amplitudes of the compound muscle and sensory action potentials and the uniform and pronounced slowing of nerve conduction in CMT1 (often in the range of 20 m/s) or near normal velocities with evidence of denervation in type 2. The CSF is usually normal. Genetic tests for the most common type 1A (PMP duplication), type 2, and for the X-linked and 1B varieties are available, and it should now be possible to identify many more cases, including sporadic ones (see Table 46-6). It is seldom necessary to resort to nerve biopsy to establish the diagnosis but on some occasions we obtained a biopsy from a patient with negative genetic testing in whom we could not exclude chronic inflammatory demyelinating polyneuropathy.

**Pathologic Findings** Degenerative changes in the nerves result in depletion of the population of large sensory and motor fibers, leaving only the condensed endoneurial connective tissue. As far as one can tell, axons and myelin sheaths are both affected, the distal parts of the nerve more than the proximal. In type I, the nerves may be enlarged, with “onion-bulb” formations of Schwann cells and fibroblasts, as in Dejerine-Sottas disease (type III HMSN in the Dyck classification). This change can often be seen in sural nerve biopsies. Anterior horn cells are slightly diminished in number and some are chromatolyzed as a secondary change. Dorsal root ganglion cells suffer a similar fate. The disease involves sensory posterior root fibers with degeneration of the posterior columns of Goll more than of Burdach. The autonomic nervous system remains relatively intact. The muscles contain large fields of atrophic fibers (group atrophy). Some of the larger fibers have a target appearance and may show degenerative changes. All these muscle changes are typical of neurogenic denervation. Claims of a coincidental myelopathy and degeneration of spinocerebellar and corticospinal tracts probably indicate that the associated disease was really Friedreich ataxia or some other combination of chronic myelopathy and neuropathy.

**Treatment** No specific treatment is known. Stabilizing the ankles by arthrodeses is indicated if foot drop is severe and the disease has reached the point where it is not progressing. Pediatric orthopedic specialists have experience with several techniques to stabilize the joints of weakened limbs. Regular exercise, but avoiding excessive weight training, is usually prescribed. In mild and early cases, fitting the legs with light braces and the shoes with springs to overcome foot drop can be helpful.

The differential diagnosis involves the distal muscular dystrophies (page 1223), late forms of familial motor system disease, Friedreich ataxia (page 931), Roussy-Lévy syndrome (see later) and other familial polyneuropathies, and, in adult onset cases, CIDP and the paraproteinemic neuropathies, discussed earlier.

**Hereditary Neuropathy with Pressure Palsies (HNPP)** This unusual but distinctive process of multiple recurrent local neuropathies first reported by Earl and colleagues is caused by a deletion of the PMP22 gene which is duplicated in the previously described CMT1A. In both CMT1A and HNPP, the PMP22 gene is functionally normal. These disorders arise because the total dose of the PMP22 protein is abnormal. In CMT1A, the gene is duplicated on one chromosome, and the total PMP22 protein is therefore predicted to be increased; by contrast, in HNPP, the gene is deleted from one chromosome, so that the PMP22 protein is predicted to be at half-normal levels. HNPP is transmitted as a dominant trait. In these individuals, the focal neuropathies and plexopathies are generally not painful (in contrast with hereditary neuralgic amyotrophy discussed further on, page 1166). Focal nerve lesions are often provoked by slight or even brief compression. In addition to recurrent focal nerve palsies, most individuals with HNPP have a chronic but slowly progressive demyelinating sensorimotor neuropathy that is mild on clinical examination (e.g., not all cases show areflexia). Electrophysiological studies are moderately abnormal with some slowing of conduction and distal motor and sensory nerve abnormalities. Nerve biopsies from these patients are most remarkable for the presence of localized nerve sheath thickening with duplication of the myelin lamellae (so-called tomaculae).

**Hypertrophic Neuropathy of Infancy (Dejerine-Sottas Disease, CMT3, or HMSN III of Dyck)** This relatively rare but striking neuropathy is inherited as an autosomal recessive trait. It begins in childhood or infancy, earlier than the classic form of peroneal muscular atrophy. Walking is delayed in onset and then progressively impaired. Pain and paresthesias in the feet are early symptoms, followed by the development of symmetrical weakness and wasting of the distal portions of the limbs. Talipes equinovarus postures with claw feet and later clawhands are common. All modalities of sensation are impaired in a distal distribution, and the tendon reflexes are absent. Miotic, unreactive pupils, nystagmus, and kyphoscoliosis have been observed in some cases. The trunk and other cranial nerves are spared. The ulnar, median, radial, posterior neck, and peroneal nerves stand out like tendons and are easily followed with the gently roving finger. The enlarged nerves are not tender. Unlike other forms of CMT, the CSF protein is persistently elevated in Dejerine-Sottas disease in all likelihood because the spinal roots are enlarged. Nerve conduction velocities are markedly reduced, even when there is little or no functional impairment. Patients are usually much more disabled than those with peroneal muscular atrophy and are confined to wheelchairs at an early age. Treatment is purely symptomatic.

It is important to emphasize that the occurrence of hypertrophic neuropathy is not confined to this particular inherited disease. If one groups all patients in whom the nerves are diffusely enlarged (incorrectly called “hypertrophic,” since it is mainly a nonspecific reaction of the epineurial and perineurial connective tissue that contributes to the bulk of the nerves), several different diseases, both genetic and acquired, are included. The identifying histologic lesion in these cases is the “onion bulb,” which consists of a whorl of overlapping, intertwined, attenuated Schwann cell processes that encircle naked or finely myelinated axons and of endoneurial fibrofilaments. Enlarged nerves have been described in cases of recurrent demyelinating polyneuritis (CIDP), familial amyloidosis, Refsum disease (HMSN type IV of Dyck), peroneal muscular atrophy type I, and other diseases. As was first pointed out by Thomas, any pathologic process that causes recurrent seg-
mental demyelination and subsequent repair and remyelination may have this effect. In some patients with a history of early childhood hereditary polyneuropathy, the nerves are not yet palpably enlarged but the characteristic Schwann cell abnormalities are revealed in biopsy material from a cutaneous nerve.

As the molecular basis of the inherited polyneuropathies has been elucidated, it has become clear that diverse molecular defects can give rise to the same clinical phenotype. From a neurobiologic perspective, it was intriguing that both Dejerine-Sottas and Roussy-Lévy syndromes were linked to a recessively inherited loss of the myelin protein P0, and that the salient clinical features of this disorder are manifestations of defective nerve myelination. However, it has also become apparent that nearly identical clinical syndromes are associated with mutations in the genes for PMP22 and for the it has also become apparent that nearly identical clinical syndromes are associated with mutations in the genes for PMP22 and for the Schwann cell deoxyribonucleic acid (DNA)-binding protein EGR2. Moreover, it is also now evident that while some mutations in the P0 gene cause infantile onset neuropathies with the Dejerine-Sottas and Roussy-Lévy phenotypes, other mutations in the same gene cause adult onset neuropathies. While the early onset cases show marked slowing of nerve conduction, the adult ones have conduction velocities that are typically above 35 m/s. The infancy-onset cases reveal major disruptions of folding of compact myelin, while in the adult-onset cases subtle alterations in the myelin protein P0 lead to a slow, predominantly axonal degeneration in adult life.

### Inherited Polyneuropathies of Predominantly Sensory Type

Common to the several diseases comprising this group is insensitivity to pain, lancinating pains, and ulcers of the feet and hands, leading to osteomyelitis, osteolysis, stress fractures, and recurrent episodes of cellulitis. Since similar symptoms and signs occur in syringomyelia, leprosy, and tabes dorsalis, there is considerable uncertainty in older writings on this subject as to whether the reported cases were examples of one of these diseases or of hereditary neuropathy. According to Dyck, it was Leplat in 1846 who first described plantar ulcers (mal perforant du pied), followed by Nelaton in 1852. Morvan in 1883 reported his observations of adult patients who had developed suppuration of the pulp of insensitive fingers (whitlows). It is now generally agreed that Morvan’s cases were examples of syringomyelia, whereas the family described by Nelaton was probably an example of the recessive form of childhood sensory polyneuropathy, since familial syringomyelia in children is practically unknown. We agree with Dyck that most such cases are examples of sensory polyneuropathy.

### Mutilating Hereditary (Dominant) Sensory Polyneuropathy in Adults (Hereditary Sensory and Autonomic Neuropathy, HSAN1)

The characteristic features of this group of polyneuropathies is an autosomal dominant mode of inheritance and onset of symptoms in the second decade or later. Characteristically this begins with subtle loss of sensation for painful stimuli in the feet (e.g., inability to feel the hot sand or hot water in a tub). As the disease evolves there is involvement of the feet with calluses of the soles and, later, episodes of blistering, ulceration, and lymphangitis followed by osteomyelitis and osteolysis, shooting pains, distal sensory loss with greater affection of pain and thermal sensation than of touch and pressure, loss of sweating, diminution or absence of tendon reflexes, and only slight loss of muscle power. Over time, loss of pain sensation in the fingers leads to fingertip ulcerations, osteomyelitis, and amputations.

The plantar ulcer overlying the head of a metatarsal bone is the most dreaded complication, since it may develop into osteomyelitis. Infection of the pulp of the fingers and paronychias are uncommon. Some patients have a mild pes cavus and weakness of the peroneal and pretibial muscles, with foot drop and steppage gait. Lancinating pains may occur in the legs, thighs, and shoulders, and, exceptionally, the pain may last for days or longer and be as disabling as that of tabes dorsalis; however, in the majority of patients there is no pain whatsoever. Neural deafness was present in one of Denny-Brown’s patients. In the latter case, which was studied postmortem, there was a loss of small nerve cells in the lumbar-sacral dorsal root ganglia; the dorsal roots were thin, and the fibers in the posterior columns of the spinal cord and those in the peripheral nerves were diminished in number. Myelinated and unmyelinated fibers were both affected. Both axonal degeneration and segmental demyelination have been demonstrated in teased nerve preparations. Sensory nerve conduction may be absent or is uniformly slowed in every nerve tested.

It must be emphasized that despite its categorization as a “sensory and autonomic neuropathy,” the most common, dominantly inherited form, termed HSAN1, also entails progressive, disabling, distal motor weakness, a consequence of ongoing axonopathy and denervation. As indicated in Table 46-6, the molecular pathogenesis of the hereditary sensory and autonomic neuropathies is beginning to be understood. It is clear, for example, that HSAN1 is a consequence of a loss of function of the enzyme serine palmitoyl transferase, which is the rate-limiting step in the biosynthesis of sphingolipids.

### Recessive Mutilating Sensory Polyneuropathy of Childhood

Here the pattern of inheritance is autosomal recessive. Onset is in infancy and early childhood and walking is delayed; there is pes cavus deformity and the first movements are ataxic. Ulcerations of the tips of toes and fingers and repeated infections of these parts result in the formation of paronychias and whitlows. The tendon reflexes are absent, but muscular power is well preserved. All sensory modalities are impaired (touch-pressure somewhat more than pain-temperature), mainly in the distal parts of the limbs but also over the trunk. In addition, there are reports of several sibships in which multiple members had a sensory neuropathy manifest by a generalized insensitivity to pain of the type described later. The lesions and electrophysiologic findings are similar to those in the dominantly inherited sensory neuropathy.

In all types of hereditary sensory neuropathy, measures must be taken to prevent stress fractures, acral mutilation, and infection. This is more difficult in the small child who does not understand the problem.

It is now evident that some of the infantile hereditary sensory neuropathies are due to a disruption of molecular signaling pathways for neurotropic substances such as nerve growth factor that are critical to neural development.

### Congenital Insensitivity to Pain

In congenital indifference to pain, a syndrome in which the patient throughout life is unreactive to the pain of injury, there is no loss of the ability to distinguish pinprick and other noxious stimuli from nonnoxious ones. Furthermore, the nervous system of such individuals seems to be normal. There is, however, another variety characterized by universal analgesia (Swanson and colleagues). This latter type is inherited as an autosomal recessive trait and at least one form involves the gene for a nerve growth factor receptor located on chromosome 1q im-
mediated adjacent to the site of the mutation for Charcot-Marie-Tooth disease type 1B (Table 46-6). During childhood, one of the patients of Swanson et al had high fever when the environmental temperature was raised, and the other possibly had orthostatic hypotension. One of the patients died in his twelfth year and was found to have an absence of small neurons in the dorsal root ganglia, an absence of Lissauer’s tracts, and a decrease in size of the descending spinal tracts of the trigeminal nerves. Sweat glands were present in the skin but were not innervated.

**Other Forms of Inherited Sensory Neuropathy** Included here are the neuropathy of Friedreich ataxia, which is discussed in Chap. 39; the Riley-Day syndrome, which is discussed further on in this chapter; neuropathy with cerebellar degeneration; and the neuropathies in which there are recognized metabolic abnormalities, including familial amyloidosis. We regularly see unclassifiable examples of an almost pure sensory or sensorimotor type. Some years ago a young man and woman with universal anesthesia affecting head, neck, trunk, and limbs came to our attention (Adams et al); all forms of sensation were absent. The patients were areflexic but retained nearly full motor power; their movements were ataxic. Autonomic functions were impaired but not abolished. In a sural nerve biopsy, nearly all fibers—large and small, myelinated and unmyelinated—had disappeared. Surprisingly, there were no trophic changes of any kind. Donaghy and others have described a unique variant of the recessively inherited form of sensory neuropathy in which there was an associated neurotrophic keratitis and a selective loss of small myelinated fibers in sural nerve biopsies. We continue to observe variant and unclassifiable cases such as these every year.

**Hereditary Areflexic Dystasia (Roussy-Lévy Syndrome, CMT3)** In 1926 Roussy and Lévy reported 7 cases of a dominantly inherited ataxic and neuropathic malady that had not previously been described. Its close relation to Friedreich ataxia and the amyotrophy of Charcot-Marie-Tooth disease was recognized. For many years thereafter the existence of this entity was disputed and, only recently, on the basis of molecular genetic testing, have these relationships been clarified.

The condition in question is a sensory ataxia (dystasia) with pes cavus and areflexia, affecting mainly the lower legs and progressing later to involve the hands. Some degree of sensory loss, mainly of vibratory and position sense, has been described in all cases. Atrophy of the muscles of the legs and postural tremor eventually become prominent. The patients do not have evidence of cerebellar disease (dysarthria, tremor, nystagmus, etc.). Kyphoscoliosis, a feature typical of Friedreich disease, has been described in several cases. Although the feet may be cold or slightly discolored, no autonomic defects are documented and the nerves are not palpably enlarged. Electrocardiographic abnormalities similar to those of Friedreich ataxia have been noted in one family but are not usual. The onset in many patients is during infancy, possibly dating from birth, and the course is relatively benign; all descendants of the original Roussy-Lévy family were still able to walk during their seventh decade of life.

On clinical and pathologic grounds, Dyck et al placed the Roussy-Lévy kinships within the category of the demyelinating type of Charcot-Marie-Tooth disease (CMT1). The mode of inheritance of the two syndromes, their benign course, pattern of neurologic signs, slow nerve conduction, and biopsy features (demyelination of nerve fibers with onion bulb formation) are much the same. This view has been reinforced by the genetic findings reported by Plante-Bordeneuve et al. In affected members of the original Roussy-Lévy family, these investigators identified a point mutation in the domain of the myelin protein gene P0, the same gene that is implicated in Dejerine-Sottas disease. Based on limited pathologic study, there is no cerebellar degeneration; nevertheless, the shared clinical features with Friedreich ataxia are unmistakable.

**Polynuropathy with Cerebellar Degeneration** (See page 934) Several such cases of adult onset have come to our attention over the years. Unlike Friedreich disease, the ataxia is mild, and there is no kyphoscoliosis but pes cavus or hammer-toe deformities are found, attesting to the early onset of the neuropathy. The lower legs become atrophic and findings characteristic of CMT such as absent ankle reflexes and mild to moderate loss of distal deep sensibility are present. There is no Romberg sign and no Babinski signs. The outstanding feature is a profound atrophy of the cerebellar hemispheres, and to some extent of the vermis, on MRI. Although the illness is slowly progressive, our patients, like those with Roussy-Lévy disease, have remained highly functional into late age, having difficulty mostly with maintaining balance while dancing or wearing high-heeled shoes. The EMG is consistent with CMT2. The electrocardiogram has been normal. Several, but not all, such patients have had a family history of a similar process but the available genetic testing has failed to reveal the site of a mutation.

**Polynuropathy with Spastic Paraplegia** From time to time we have observed children and young adults with unmistakable progressive spastic paraplegia superimposed on a sensorimotor polyneuropathy of extremely chronic evolution. Sural nerve biopsy in two of our cases disclosed a typical “hypertrophic” polynuropathy. In another case only loss of nerve fibers was found. Cavanaugh and colleagues and Harding and Thomas have reported similar patients. Our patients were severely disabled, being barely able to stand on their atrophic legs. The disease is slowly progressive. The patients described by Cavanaugh and coworkers had mainly sensory deficits and were not disabled. A more ambiguous form of disease has been described by Vucic and colleagues in which there is typical CMT but with brisk reflexes. There were Babinski signs in half the patients and spastic dysphonia in a few others. The mutation is not known.

While few in number, some cases of chronic polynuropathy are combined with optic atrophy, with or without deafness or retinitis pigmentosa, and Dyck has classed these in a separate group. Jaradeh and Dyck have also described a hereditary motor-sensory polynuropathy with the later development of a parkinsonian or a choreic-dystonic syndrome that responded to L-dopa. Most cases of this type have had an autosomal recessive inheritance.

**Hereditary Recurrent Brachial Plexopathy (Hereditary Neurolgic Amyotrophy, HNA)** This entity, mentioned earlier in relation to hereditary neuropathy with pressure palsies because of the implication of a similar genetic locus, is discussed in a later section of the chapter under “Brachial Neuritis.”

**Inherited Polynuropathies with a Recognized Metabolic Disorder**

**Refsum Disease** (Heredopathia Atactica Polyneuritiformis; HMSN IV) This rare disorder, named after Refsum who made the first clinical observations, is inherited as an autosomal recessive
trait and has its onset in late childhood, adolescence, or early adult life. Diagnosis is based on a combination of clinical manifesta-
tions—retinitis pigmentosa, cerebellar ataxia, and chronic poly-
neuropathy—coupled with the metabolic marker of the disease, an
increase in blood phytic acid. Phytic acid accumulates because of
a deficiency of the peroxisomal enzyme, phytanoyl-CoA hy-
droxylase. The deficiency is caused by mutations in one of two
disparate genes. Cardiomyopathy and neurogenic deafness are
present in most patients, and pupillary abnormalities, cataracts, and
ichthyotic skin changes (particularly on the shins) are added fea-
tures in some. Anosmia and night-blindness with constriction of
the visual fields may precede the neuropathy by many years. The
polyneuropathy is sensorimotor, distal, and symmetrical in distri-
bution, affecting the legs more than the arms. All forms of sensation
are reduced, often deep sensation more so than pain and thermal
sense, and tendon reflexes are lost. The CSF protein is increased,
sometimes markedly. Usually, the polyneuropathy develops gradu-
ally, although in some patients it has a subacute onset or, after
being established for some time, a tendency to worsen fairly
abruptly.

Although the nerves may not be palpably enlarged, “hyper-
trophic” changes with onion bulb formation are variable patho-
logic features. The metabolic defect has been discovered to be in
the utilization of dietary phytol; a failure of oxidation of phytanic
acid—a branched-chain tetramethylated 16-carbon fatty acid—ac-
cumulates in the absence of activity of the enzyme phytanoyl-CoA-
hydroxylase. The relation between the increased phytic acid and
the polyneuropathy is uncertain.

Clinical diagnosis is confirmed by the finding of increased
phytanic acid in the blood of a patient with a chronic, mainly sen-
sory neuropathy; the normal level is less than 0.3 mg/dL but in
patients with this disease it constitutes 5 to 30 percent of the total
fatty acids of the serum lipids. Urinary phytic acid concentration
is also raised.

Treatment Diets low in phytol may be beneficial, but this is dif-
ficult to judge, for after an acute attack there is sometimes a natural
remission. The effects of plasma exchange have also been difficult
to interpret. In some patients there is a very slow and gradual pro-
gression of the disease and in others a more rapid progression with
death from cardiac complications.

Neuropathy, Ataxia, and Retinitis Pigmentosa, without In-
crease in Phytic Acid (NARP) Like the cases reported by
Tuck and McLeod, we have observed several in which the clinical
picture was almost identical to that of Refsum disease but eleva-
tions in phytic acid could not be detected. A mild ichthyosis,
sensorineurial deafness, ataxia of mixed tabetic-cerebellar type,
areflexia, and retinitis pigmentosa were the main findings. None of
our cases had a positive family history. Sural nerve biopsy showed
loss of large fibers. Biochemical abnormalities in the blood or cul-
tured fibroblasts have not been detected. There has been an iden-
tifiable mitochondrial disorder in most of the recently studied cases.
This probably represents a variant of the so-called NARP syn-
drome, as described on page 844. It should be remarked that most
mutations of mitochondrial DNA cause a myopathy with multisys-
tem disease, but not a neuropathy. The onset of the disease has
been in childhood or adolescence with slow progression.

Abetalipoproteinemia (Bassen-Kornzweig Syndrome; See also
page 827) This rare autosomal recessive childhood disorder has
been described in Chap. 37 with the inherited metabolic disorders
of the nervous system. It is mentioned here because the brunt of
the neurologic disorder falls upon the peripheral nerves. Acanth-
ocytoisis of red blood cells is its identifying feature. The earliest
neurologic finding is usually diminution or absence of tendon re-
flexes, detected as early as the second year of life. Later, when the
patient is first able to cooperate in sensory testing, a loss of vibra-
tory and position sense is found in the legs. Cerebellar signs (ataxia
of gait, trunk, and extremities; titubation of the head; and dysar-
thria), muscle weakness, ophthalmoparesis, Babinski signs, and
loss of pain and temperature sense are the other characteristic neu-
rologic abnormalities, in more or less this order of frequency. Men-
tal backwardness occurs in some patients. There are no signs of
autonomic disorder. Irregular progression occurs over a few years
and many patients are unable to stand and walk by the time they
reach adolescence. (There is no relationship to acanthocytosis with
chorea.)

Skeletal abnormalities include pes cavus and kyphoscoliosis,
which are secondary to the early-onset neuropathy. Constriction of
the visual fields and ring scotomata are manifestations of the mac-
ular degeneration and retinitis pigmentosa in some cases. Cardiac
enlargement and congestive failure are serious late complications.

Neuropathologic findings consist of demyelination of periph-
eral nerves and degeneration of nerve cells in the spinal gray matter
and cerebellar cortex. Diagnosis is confirmed by the finding of red
blood cell acanthocytes, low serum cholesterol, and \( \beta \) (low-den-
sity)-lipoproteins. The disease is caused by defects in a triglyceride
transfer protein, as discussed in Chap. 37. A deficiency of vitamin
E, due to malabsorption, may be a factor, and large doses of the
vitamin should be tried as therapy.

A closely related disease, also with familial hypobetalipopro-
teinemia, has been described by van Buchem and coworkers. It too
is associated with malabsorption syndrome, ill-defined weakness,
ataxia, dysesthesia of the legs, and Babinski signs. There is no
sensory loss.

Tangier Disease This is a rare familial disorder of which we have
seen four cases, inherited as an autosomal recessive trait. It is
named for the island off the Virginia coast where the first-described
patients resided. The genetic abnormality eliminates the function
of the so-called ATP-cassette transporter protein. It results in a
deficiency of high-density lipoprotein, low serum cholesterol, dim-
ution of phospholipids, and high triglyceride concentrations in
the serum. Perhaps because of these abnormalities, the patients are
disposed to early and severe atherosclerosis. The presence of en-
larged, yellow-orange (cholesterol-laden) tonsils is said to be a fre-
cquent manifestation (two of our patients had had previous tonsillec-
tomies so that this sign was not evident). About half of the reported
cases have had neuropathic symptoms, taking the form of an asym-
metrical sensorimotor neuropathy that fluctuates in severity.

The sensory loss is predominantly for pain and temperature
and extends over the entire body; at times it is limited to the face
and upper extremities simulating syringomyelia (pseudosyringo-
myelia). Tactile and proprioceptive sensory modalities tend to be
preserved. The polyneuropathy may come in attacks—that is to
say, it is recurrent. In the two sisters reported by Engel and co-
workers, the onset of symptoms was in childhood and in infancy,
respectively. Muscular weakness, if present, affects either the lower
or upper extremities or both, particularly the hand muscles, which
may undergo atrophy and show denervation by EMG. In a small
number of patients there has been facial diplegia out of proportion
to weakness elsewhere. In one of our patients, the pain and tem-
temperature loss was restricted to the head, neck, and arms. Nerve conduction is slowed. Tendon reflexes are often lost or diminished. Transient ptosis and diplopia have been reported.

Fat-laden macrophages are present in the bone marrow and elsewhere. No complete pathologic studies are available. There is no known treatment. Dietary measures to reduce triglycerides may help, particularly in preventing atherosclerosis, but whether they influence the neuropathy is uncertain.

**Fabry Disease (Anderson-Fabry Disease; See also page 839)**

The genetic and metabolic aspects of this sex-linked disorder caused by deficiency of β-galactosidase have already been considered with the inherited metabolic diseases. Here we offer some additional remarks about the painful neuropathic component. It bears commenting that 10 percent of heterozygotic women display neuropathic symptoms, but usually of later onset and lesser degree than in males.

The pain, which is usually the initial symptom in childhood and adolescence, often has a burning quality or occurs in brief lancinating jabs, mostly in the fingers and toes and may be accompanied by paresthesias of the palms and soles. Changes in environmental temperature and exercise may induce pain in “crises,” an identifying feature. These abnormalities are due to the accumulation of glycolipid (ceramide trihexoside) in peripheral nerves, both perineurally and intraneurally, as well as in cells of the spinal ganglia and the anterior and intermedialateral horns of the spinal cord. Ohnishi and Dyck have demonstrated a preferential loss of small myelinated and unmyelinated fibers and small neurons of dorsal root ganglia and Cable and colleagues reported autonomic changes in other cases. Involvement of the sensory ganglia and the associated degenerative changes in the afferent fibers are thought to be the likely cause of the thermally induced painful sensory phenomena (Kahn).

Later in the illness there is progressive impairment of renal function and cerebral and myocardial infarction. The characteristic dermal feature is the presence of numerous dark red macules and angiokeratomas, up to 2 mm in diameter, over the trunk and limbs, most closely clustered over the thighs and lower trunk and around the umbilicus (angiokeratoma corporis diffusum). The comprehensive review by Brady and Schiffman is recommended.

**Treatment**

Phenyltoin, carbamazepine, or gabapentin and amitriptyline may be helpful in alleviating the pain and dysesthesias. As discussed in Chap. 38, enzyme replacement therapy has become available and seems to lead to partial remission of many of the features.

**Polyneuropathy of Acromegaly and Gigantism**

Nerve entrapment, particularly of the median nerve, is a well-known feature of acromegaly. Pickett and colleagues identified carpal tunnel syndrome in 56 percent of acromegals. Also recognized as a complication of acromegaly, but not due to multiple nerve entrapments, is polyneuropathy characterized by paresthesias, loss of tendon reflexes in the legs, and atrophy of slight degree in the distal leg muscles. Sometimes there are enlarged nerves. In the case reported by Stewart, the enlargement was the result of hypertrophic changes in the endoneurial and perineurial tissues, similar to those that occur in other so-called hypertrophic neuropathies of inflammatory or heredofamilial origin. In cases of extreme gigantism, a more severe polyneuropathy has sometimes been reported, to the point of causing Charcot joints (Daughady).

Mentioned here is a case we have observed in which a severe but slowly progressive motor neuropathy occurred in a patient with Pyle disease, a metaplasia dysplasia that resembles acromegaly.

**Metachromatic Leukodystrophy** (See also Chap. 37)

In this disease, the congenital absence of the degradative enzyme sulfatase leads to massive accumulation of sulfatide throughout the central and peripheral nervous systems and to a lesser extent in other organs. The abnormality is transmitted as an autosomal recessive trait. Progressive cerebral deterioration is the most obvious clinical feature, but hyporeflexia, muscular atrophy, and diminished nerve conduction velocity reflect the presence of a neuropathy. Early in the course of the illness, the weakness, hypotonia, and areflexia may suggest Werdnig-Hoffmann disease; in older children there may be a complaint of paresthesias and demonstrable sensory loss. Biphasic weakness has been reported but must be rare. Sensory and motor conduction velocities are slowed. Metachromatically staining granules accumulate in the cytoplasm of Schwann cells in all peripheral nerves as well as in the cerebral white matter. There is also a loss of myelinated fibers. The measurement of arylsulfatase A activity in peripheral leukocytes or urine and biopsies of sural nerves are used to establish the diagnosis, even early in the course of the illness.

**Riley-Day Familial Dysautonomia** (See also Chap. 26)

This disorder, inherited as an autosomal recessive trait, affects Jewish children predominantly. Familial dysautonomia is usually manifested at birth (poor sucking, failure to thrive, unexplained fever, episodes of pneumonia). Hyporeflexia and impairment or loss of pain and temperature sensation, with relative preservation of pressure and tactile sense, are the main neuropathic manifestations. Motor fibers are probably involved as well, but only to a slight degree; this is shown more effectively by reduced motor conduction velocity in peripheral nerves than it is by weakness. At a later age the neuropathy becomes overshadowed by other manifestations of the disease, notably repeated infections and abnormalities of the autonomic nervous system—lack of tears, corneal ulceration, fixed pupils, blotchiness of the skin, defective temperature control, cold hands and feet, excessive sweating, lability of blood pressure, postural hypotension, difficulty in swallowing, esophageal and intestinal dilatation, emotional instability, recurrent vomiting, and stunted growth. The tongue lacks fungiform papillae.

Nerve biopsy reveals a diminution of small myelinated and unmyelinated fibers, which explains the impairment of pain and temperature sensation. In autopsy material, sympathetic and parasympathetic ganglion cells and, to a lesser extent, nerve cells in the sensory ganglia are diminished in number. Patients excrete increased amounts of homovanillic acid and decreased amounts of vanillylmandelic acid and methoxy-hydroxyphenylglycol. Weinsilboum and Axelrod demonstrated a significant decrease in serum dopamine β-hydroxylase, the enzyme that converts dopamine to norepinephrine. The disease is caused by a mutation in a gene that expresses a kinase-associated protein (Table 46-6). There is no treatment for the disease except to provide symptomatic relief of gastrointestinal symptoms and orthostatic fainting.

Other examples of congenital polyneuropathy with absence of autonomic function, probably differing from the Riley-Day dysautonomia, have been reported. Some of these, in our experience, develop transient episodes of reflex sympathetic dystrophy. A congenital failure of development of neural elements derived from the neural crest is postulated.
Ataxia telangiectasia and Chédiak-Higashi disease are other genetic diseases with a recognized metabolic abnormality that may cause a polyneuropathy. They are described in Chap. 37, with the hereditary metabolic disorders.

Inherited (FA) Amyloid Neuropathies (See Table 46-6) As noted earlier in the discussion of acquired (primary) amyloidosis, amyloid is a descriptive term for any of the proteins that are deposited in filamentous beta-pleated sheets; it can be derived from a number of precursor protein sources. Peripheral neuropathy is a common and often the most prominent manifestation of amyloidosis. The polyneuropathies are of two main types—those associated with familial amyloidosis (referred to as FA) and the other associated with primary (nonfamilial) systemic deposition of amyloid (termed AL), which is derived from a circulating monoclonal protein. The acquired type has been discussed earlier under “Polyneuropathy Associated with Paraproteinemia.” The most notable difference between these two types is the absence of a significant amount of paraprotein in the inherited forms (see further on). As also commented earlier in the chapter, the amyloidosis that is secondary to chronic suppurative or inflammatory disease, referred to as AA, is an increasingly rare condition and, in any case, does not affect the nerves.

The familial amyloid polyneuropathies comprise several distinct groups (Table 46-6). The pattern of inheritance in all types is autosomal dominant; males and females are affected with equal frequency. Although a descriptive classification based on the ethnic origin of affected families is still in use clinically, it is now possible to categorize the diseases according to their genetic causes and the corresponding chemical structure of the abnormal protein that is deposited in the tissue as amyloid. The recent cloning of many of the amyloid protein genes has made possible not only the detection of the common transthyretin gene abnormality but should also make available diagnostic DNA tests for the other types of familial amyloidosis in the near future (see Table 46-6). Lachmann and colleagues emphasize the high frequency of genetic defects in amyloid precursor proteins and the finding in one quarter of cases of a low-level monoclonal gammopathy. Our cases have not shown a paraprotein.

Characteristic of all the amyloid polyneuropathies is the preferential involvement of small-diameter sensory and autonomic nerves and deposition of amyloid in various organs. Sensory loss, therefore, dominates the picture and pain and autonomic changes are prominent in most varieties of the disease.

The following are the recognized types of familial amyloid neuropathy.

1. The Portuguese (Andrade) type Andrade, in 1939, recognized that a chronic familial illness known as “foot disease” among the inhabitants of Oporto, Portugal, was a special type of amyloid polyneuropathy. He was not the first to have seen amyloid in degenerating nerve but deserves credit for identifying the disease as one of the heredofamilial polyneuropathies. By 1969 he had studied 148 sibships, comprising 623 individuals, among whom there were 249 with polyneuropathy. Descendants of this family have been traced to Africa, France, and Brazil. Other foci of the disease have been reported in Japan (Araki et al; Ikeda et al), the United States (Kantarjian and DeJong), Germany (Delank et al), Poland, Greece, Sweden, and northwest Ireland (Staunton and others). As far as one can tell, these are separate, unrelated probands in different ethnic groups.

The age of onset of this form of familial amyloid polyneuropathy is between 25 and 35 years. The disease progresses slowly and terminates fatally in 10 to 15 or more years. The initial symptoms are usually numbness, paresthesias, and sometimes pain in the feet and lower legs. Weakness is minimal, and the tendon reflexes, although diminished, may be retained early in the course of the illness. Pain and thermal sense are reduced more than tactile, vibratory, and position sense (a “pseudosyrinxomyelic”) pattern. Autonomic involvement is another important characteristic—loss of pupillary light reflexes and miosis, anhidrosis, vasomotor paralysis with orthostatic hypotension, alternating diarrhea and constipation, and impotence. These autonomic changes tend to be more extensive than the sensory ones. Difficulty in walking also develops and has its basis in a combination of faulty position sense and mild muscle weakness. Later, tendon reflexes are abolished and the legs become thin. The nerves are not enlarged. Cranial nerve involvement (facial weakness and numbness, loss of taste) is a late manifestation and occurs in only a few cases.

Cases vary somewhat. Cardiac enlargement and irregularities in cardiac rhythm due to bundle branch or atrioventricular (AV) block occur early in some and late in others. A few patients have had severe amyloid heart disease from the onset (Ikeda et al). Weight loss may be pronounced, owing to anorexia and disordered bowel function and the later development of a malabsorption syndrome. The liver may become enlarged (as it may in the acquired form). Vitreous opacities (veils, specks, and strands) may progress to blindness, but this has been rare; in a few, there has been an impairment of hearing. Involvement of the CNS—manifest as behavioral abnormalities, cerebellar ataxia, and bilateral corticospinal signs—has also been reported in a few cases, but their nature and pathologic basis is controversial (Ikeda et al). A nephrotic syndrome and uremia terminate life in some patients. The CSF may be normal or the protein content may be increased (50 to 200 mg/dL); the blood is normal except for anemia caused by amyloidosis of the bone marrow.

In this and the following most common familial amyloidoses, the amyloid is derived from an inherited abnormality of serum protein transthyretin (formerly called “prealbumin”). Several different amino acid substitutions have been identified in each group. In the originally described Andrade type, methionine replaces valine at amino acid 30; this has therefore been referred to as transthyretin amyloidosis.

2. Familial amyloidosis with carpal tunnel syndrome (Swiss type) Falls and coworkers in 1955 and later Rukavina and associates described a large group of patients of Swiss stock living in Indiana who developed, in their fourth and fifth decades, a characteristic syndrome of acroparesthesias in the hands due to deposition of amyloid in the connective tissues and beneath the carpal ligaments. Similar kindreds, of German descent, were recognized in Maryland. There was sensory loss and atrophic muscle weakness in the distribution of the median nerves, which were compressed. Section of the carpal ligaments relieved the symptoms. In some of the patients, other nerves of the arms were said to have become involved later. Vitreous deposits have been observed
frequently in this form of the disease. As with the Portuguese type, an abnormal transthyretin is the basis of the deposition of amyloid.

3. Iowa type In 1969, van Allen described an Iowa kindred with onset, in their 30s, of a fairly severe sensorimotor neuropathy, involving the legs and then the arms. There was amyloid deposition in the testes, adrenal glands, and kidneys (the usual cause of death) as well as a high incidence of peptic ulcer disease. The amyloid in this disease is derived from apolipoprotein A-1, in which there is an amino acid substitution.

4. Cranial neuropathy with corneal lattice dystrophy This unusual form of amyloid neuropathy was first described in three Finnish families by Meretoja—hence the label “Finnsih type.” Subsequently, it was reported from several different parts of the world in families of non-Finnish heritage. This disease usually begins in the third decade, with lattice corneal dystrophy. Vitreous opacities are not observed, and visual acuity is little affected. Peripheral neuropathy may not be evident until the fifth decade, at which time the facial nerves, particularly their upper branches, become affected. The nerves of the limbs are involved even later and to a much lesser extent than in other amyloid neuropathies. In advanced cases there is a distinctive appearance of excessive skin folds about the face, facial diparesis, dysarthria, spasticity, and dense loss of posterior column function. At postmortem examination, deposits of amyloid are found in virtually every organ, but mainly in the kidneys and blood vessels and in the perineurium of affected nerves.

The amyloid fibrils are derived from the protein gelsolin. The latter is normally an actin-binding protein, but it is also an important constituent of basement membranes, which may explain the deposition of amyloid in the cornea and skin.

**Diagnosis** When the characteristic painful small-fiber type of sensory disturbance and autonomic changes are coupled with a family history of the same constellation, the diagnosis is not difficult. As noted in the earlier section on the acquired paraproteinemic neuropathy, the presence of a monoclonal (rarely polyclonal) immunoglobulin in the blood is found in only a limited number of patients with familial amyloid cases and it is of a low quantity, usually just above the upper limit of normal for the immunoglobulin subclass. Otherwise, as noted by several authors, the two types of amyloid disease are quite similar and, indeed, about 10 percent of cases thought to be acquired will in the end be found to have the genetic disorder (Lachmann et al). The situation has been rectified to some extent by the availability of gene sequencing to detect mutations related to amyloid. These tests are now performed by several commercial laboratories. Such testing is justified if there is a low concentration paraprotein (or none) and a typical amyloidotic polyneuropathy and when the family history does not point to the correct diagnosis.

**Pathologic Findings** Amyloid deposits are demonstrable in the walls of blood vessels, the interstitial (endoneurial) tissues of the peripheral somatic and autonomic nerves, and in the spinal and autonomic ganglia and roots. There is a loss of nerve fibers, the unmyelinated and small myelinated fibers being more depleted than the large myelinated ones. The anterior horn and sympathetic ganglion cells are swollen and chromatolysed due to involvement of their axons, and the posterior columns of the spinal cord degenerate, also on a secondary basis.

The pathogenesis of the fiber loss in familial amyloidosis, as in the acquired type, is not fully understood. On the basis of their findings in a sporadic case of amyloid polyneuropathy with diabetes mellitus, Kernohan and Woltman suggested that amyloid deposition in the walls of the small arteries and arterioles interfered with the circulation in the nerves and that amyloid neuropathy is essentially an ischemic process. In other cases, however, the vascular changes are relatively slight and the degeneration of the nerve fibers appears to be related to their compression and distortion by the endoneurial deposits of amyloid or, alternatively, there may be a direct toxic effect of the embedded amyloid. Amyloid is also seen in the tongue, gums, heart, gastrointestinal tract, kidneys, and many other organs, where it may act as a tissue toxin or has a mechanically disrupting effect on cells.

**Treatment** Liver transplantation has in recent years proved curative of some of the familial amyloid polyneuropathies but obviously it has no role in the acquired forms. According to Herlenius and colleagues, over 500 patients have received liver transplants for this disease with a 77 percent rate of survival, equivalent to liver transplantation for other diseases.

**Neuropathies Associated with AIDS** (See Chap. 33) Patients infected with HIV are prone to several types of neuropathy, including a predominantly sensory type that may be painful, a lumbar sacral polyradiculopathy, cranial (mainly facial nerve) and limb mononeuropathies, CIDP, GBS, and a vasculitic mononeuritis multiplex—none of which differs from the idiopathic or conventional varieties except that there is often a pleocytosis in the spinal fluid. Unique but not infrequent patterns in this group are the CMV cauda equina neuritis syndrome and an acute or subacute painful infiltrative lymphocytic neuropathy—a component of the diffuse infiltrative lymphocytosis (DILS; Moulanger et al). Polyneuropathy may also be induced by antiviral agents that are used in the treatment of HIV infection, as discussed in Chap. 33.

**Problems in Diagnosis of the Chronic Polyneuropathies** This is the group of peripheral nerve diseases that has given the present authors the most difficulty. The cause of most of the acute and many of the subacute and relapsing forms usually can be established by the clinical and laboratory methods presently available in large centers. It is the early and late chronic polyneuropathies that continue to baffle the neurologist and general physician, despite the respectable advances that have been made in the field of genetic testing.

**Diagnosis of Early Chronic Polyneuropathies** A sensorimotor paralysis, which evolves over several weeks (subacutely) or more slowly, over many months or a year or two, and involves legs more than arms and distal parts more than proximal should, in an adult, always lead to a search for diabetes, occult neoplasia (carcinoma, lymphoma, multiple myeloma, or plasmacytoma), HIV infection, paraproteinemia (including amyloid neuropathy), connective tissue disease, and CIDP. In exceptional cases, a neoplastic process remains hidden for as long as 2 or 3 years after the onset of neuropathy. In our experience an environmental toxin, endocrine disorder (except for diabetes), or nutritional cause is seldom identified, de-
spite the frequent attribution of obscure polyneuropathies to such causes. Nonetheless, history of exposure to industrial or hobbyist toxins, sociopathy or psychopathy that would lead to toxin ingestion, or foreign travel should be sought and the evaluation should include testing for heavy metals in obscure cases. Unusual causes of nutritional deficiency such as celiac-sprue disease and other malabsorption syndromes (Whipple disease, Crohn disease, chronic hepatic disease, intestinal bypass surgery) have usually been obvious enough when present, so that the experienced clinician rarely overlooks them. Perhaps sprue is able to cause a neuropathy with minimal gastrointestinal symptoms. Vitamin B₁₂ deficiency should be sought in cases of large-fiber neuropathy. A difficult problem is that of an older person with a mild, nonprogressive sensorimotor polyneuropathy in whom there is evidence of mild hypothyroidism, that of an elderly patient was discussed earlier on page 1151. Rarely, a milder sensory neuropathy may be seen with biliary cirrhosis. When the symptoms are confined to the feet and legs, hereditary sensory neuropathy must always be considered if the condition is long standing.

In the purely or predominantly sensory polyneuropathies not due to diabetes—some painful, some not, and some with marked ataxia—an association with occult carcinoma, an IgM or other paraproteinemias, amyloidosis, or Sjögren syndrome are the primary considerations. The problem of a mild sensory neuropathy in an elderly patient was discussed earlier on page 1151. Rarely, a milder sensory neuropathy may be seen with biliary cirrhosis. When the symptoms are confined to the feet and legs, hereditary sensory neuropathy must always be considered if the condition is long standing.

Intoxications with pyridoxine or metals account for a few chronic sensory neuropathies. Despite all these considerations, we still regularly encounter patients in whom the cause is not disclosed by any of the available tests. We have watched helplessly as some of these patients become reduced to a bed and wheelchair existence and others suffer from pain until they turn to and become dependent on opiates.

In our experience, the subacute and chronically evolving demyelinating neuropathies that are suspected clinically and then confirmed by slowed conduction velocity, conduction block, and relatively normal needle EMG studies generally turn out to be variants of CIDP, some with a paraproteinemias. Often the electrophysiologic tests point to a combined axonal and demyelinating process, the latter reflected in prolonged distal latencies, conduction slowing or block, and loss of late responses. Marked weakness and reduced muscle action potential amplitudes in the face of minimal denervation, even if present in only a few nerves, also indicate at least a component of focal demyelination. Most of the mixed axonal-demyelinating cases in which one eventually arrives at a diagnosis will also be related to an immune (paraproteinemic) or inflammatory (CIDP) process; for the moment, it is useful to place these in the demyelinating category since many will respond to the same measures as are used in the treatment of purely demyelinating CIDP.

Laboratory tests that are useful in the investigation of this group of neuropathies are listed in Table 46-7.

* The use of each test is guided by clinical circumstances.

Diagnosis of Late Chronic Polyneuropathies  The majority of the more chronic and very gradually progressive polyneuropathies (i.e., evolving over 10 or more years) prove to be heredofamilial or sporadic mutations of the genes that are responsible for the inherited types. The observations of Dyck and coworkers, referred to in the introduction to this chapter, are of interest in this respect. In a series of 205 patients who were referred to the Mayo Clinic with neuropathies of unknown cause, 86 were found to have an inherited form of the disease. With appropriate genealogic data, the diagnoses of the hypertrophic polyneuropathy of Dejerine-Sottas and the peroneal muscular atrophy of Charcot-Marie-Tooth can usually be made on clinical grounds alone (high arches, chronicity, etc.).

Sporadic cases are more difficult. Many of the patients who have consulted us in adulthood for an obscure polyneuropathy report having had operations on their feet for these reasons but the connection to a genetic neuropathy had not been previously made. Additional hints are frequent sprained ankles and the need to tape the ankles during adolescence in order to run or participate in sports. Dyck and associates found that direct examinations of the patients’ children, parents, and other close relatives—using all available clinical data, EMG, nerve conduction studies, CSF examination, and nerve and muscle biopsy—were often successful in revealing a hereditary basis for the neuropathy. We, too, have found that in perplexing cases, routine examination of other family members, searching specifically for dropped ankle jerks and muted-knee reflexes, foot abnormalities, or atrophy of leg muscles, has clarified the diagnosis. DNA testing for the classic forms of Charcot-Marie-Tooth disease is now available from commercial laboratories and has increased the diagnostic certainty.

Slowly progressive polyneuropathy with features of central
nervous system degeneration, particularly cerebellar ataxia, most often has a genetic basis but a small number are found to be due to a genetic metabolic disorder such as a leukodystrophy.

In contrast, a few young patients have come to our attention in whom a gradually progressive polyneuropathy that evolved over almost a decade turned out to be an acquired chronic inflammatory demyelinating condition rather than the expected genetic type. The absence of a family history of neuropathy or of high arches, and heterogeneous slowing of both nerve conduction velocities and reductions in motor amplitudes on the EMG, provided hints to the acquired nature of the condition.

Finally, it should be conceded again that even after the most assiduous clinical and laboratory investigation of patients with chronic neuropathy, at least one quarter of these disorders remain unexplained.

### Problems in Diagnosis of Recurrent or Relapsing Polyneuropathy

Several types of neuropathy are particularly prone to recurrence: CIDP, Refsum disease, Tangier disease, and porphyria, in which the attacks recur spontaneously or are precipitated by the administration of barbiturates or other drugs. Repeated toxic exposure can do the same. Approximately 2 percent of patients with GBS have one or more relapses, in which the clinical and pathologic changes differ in no meaningful way from those of the acute monophasic form of the disease. Some instances of mononeuritis multiplex, especially when associated with cryoglobulinemia, are characterized by remission and relapse over many years, although the remissions are incomplete. A common cause of relapse is the withdrawal of corticosteroids in CIDP patients who are dependent on these drugs; similarly, lapses in the treatment of paraproteinemic neuropathies cause similar fluctuations in symptoms. Enlargement of nerves may occur with repeated attacks, and it is probable that some patients classed originally as having one form of Dejerine-Sottas hypertrophic neuropathy fall into this category. Also, it is obvious that patients who have recovered from an episode of alcoholic-nutritional or toxic polyneuropathy will develop a recurrence of their disease if they again subject themselves to intoxication or nutritional deficiency.

Neuropathic symptoms that fluctuate in relation to environmental factors such as cold (cryoglobulinemia), heat (Fabry and Tangier diseases), or intermittent exposure to heavy metal or other type of poisoning may simulate an inherently relapsing polyneuropathy.

---

**MONONEUROPATHY, MONONEUROPATHY MULTIPLEX, AND PLEXOPATHY**

The distinguishing feature of this group of neuropathies is that either one or several individual peripheral nerves or a plexus are involved by a disease process. The diagnosis rests on the finding of motor, reflex, or sensory changes confined to the territory of a single nerve; of several individual nerves affected in a random manner (mononeuritis or mononeuropathy multiplex); or of a plexus of nerves or part of a plexus (plexopathy). Certain neuropathies of this type—traceable to polyarteritis nodosa and other vasculitides, leprosy, sarcoi...
Figure 46-5. Diagram of the brachial plexus: the components of the plexus have been separated and drawn out of scale. Note that peripheral nerves arise from various components of the plexus: roots (indicated by cervical roots 5, 6, 7, and 8 and the first thoracic nerve root); trunks (upper, middle, lower); divisions (anterior and posterior); and cords (lateral, posterior, and medial). The median nerve arises from the heads of the lateral and medial cords. (From Haymaker and Woodhall by permission.)

preserved sensory potentials in nerves that are unaffected central to the ganglion. MRI may expose infiltrative lesions of the plexus, but small nodular lesions may escape detection and one then defers to the clinical data if the circumstances suggest an infiltrative or compressive lesion.

For the anatomic plan of the brachial (and lumbosacral) plexus and their relations to blood vessels and bony structures, Fig. 46-5 and one of the more detailed monographs on the peripheral nerves should be consulted. For the illustration of individual nerves, the manual of Devinsky and Feldmann and the one published by the Guarantors of Brain listed in the references proved helpful.

For quick orientation, it is enough to remember that the brachial plexus is formed from the anterior and posterior divisions of cervical roots 5, 6, 7, and 8 and the first thoracic nerve roots. The fifth and sixth cervical roots merge into the upper trunk, the seventh root forms the middle trunk, and the eighth cervical and first thoracic roots form the lower trunk. Each trunk divides into an anterior and posterior division. The posterior divisions of each trunk unite to form the posterior cord of the plexus. The anterior divisions of the upper and middle trunks unite to form the lateral cord. The anterior division of the lower trunk forms the medial cord. Two important nerves emerge from the upper trunk (dorsal scapular nerve to the rhomboid and levator scapula muscles, and long thoracic nerve to the anterior serratus). The posterior cord gives rise mainly to the radial nerve. The medial cord gives rise to the ulnar nerve, medial cutaneous nerve to the forearm, and medial cutaneous nerve to the upper arm. This cord lies in close relation to the subclavian artery and apex of the lung and is the part of the plexus most susceptible to traction injuries and to compression by tumors that invade the costoclavicular space. The median nerve is formed by the union of parts of the medial and lateral cords.

Lesions of the Whole Plexus The entire arm is paralyzed and hangs uselessly at the side; the sensory loss is complete below a line extending from the shoulder diagonally downward and medially to the middle third of the upper arm. Biceps, triceps, radial, and finger reflexes are abolished. The usual cause is vehicular trauma.

Upper Brachial Plexus Paralysis This is due to injury to the fifth and sixth cervical nerves and roots, the most common causes of which are forceful separation of the head and shoulder during difficult delivery, pressure on the supraclavicular region during anesthesia, immune reactions to injections of foreign serum or vaccines, and idiopathic brachial plexitis (see later). The muscles affected are the biceps, deltoid, supinator longus, supraspinatus and infraspinatus, and, if the lesion is very proximal, the rhomboids. The arm hangs at the side, internally rotated and extended at the elbow. Movements of the hand and forearm are unaffected. The prognosis for spontaneous recovery is generally good, though this may be incomplete; injuries of the upper brachial plexus and spinal roots incurring at birth (Erb-Duchenne palsy) may persist throughout life.

Lower Brachial Plexus Paralysis This is commonly the result of traction on the abducted arm in a fall or during an operation on the axilla, infiltration or compression by tumors extending from the apex of the lung (superior sulcus or Pancoast syndrome), or compression by cervical ribs or bands. Injury may occur during birth, particularly with breech deliveries (Dejerine-Klumpke paralysis). There is weakness and wasting of the small muscles of the hand and a characteristic clawhand deformity. Sensory loss is limited to the ulnar border of the hand and the inner forearm; if the first thoracic motor root is involved, there may be an associated paral-
ysis of the cervical sympathetic nerves with a Horner syndrome. Invasion of the lower plexus by tumors is usually painful; postradiation lesions are more likely to cause paresthesias without pain (Lederman and Wilbourn).

**Infraclavicular Lesions Involving Cords of the Brachial Plexus**  
(See Fig. 46-5) A lesion of the lateral cord causes weakness of the muscles supplied by the musculocutaneous nerve and the lateral root of the median nerve; it manifests mainly as a weakness of flexion and pronation of the forearm. The intrinsic muscles of the hand innervated by the medial root of the median nerve are spared. A lesion of the medial cord of the plexus causes weakness of muscles supplied by the medial root of the median nerve and the ulnar nerve. The effect is that of a combined median and ulnar nerve palsy. A lesion of the posterior cord results in weakness of the deltoid muscle, externators of the elbow, wrist, and fingers, and sensory loss on the outer surface of the upper arm.

One group of infraclavicular injuries, often iatrogenic, results from damage to the subclavian or axillary vessels and the formation of pseudoaneurysms or hematomas. Small puncture wounds—as might occur with catheterization of the subclavian vein, anesthetic block of the brachial plexus, or transaxillary arteriography—are likely to produce this type of injury. Compression of the plexus usually evolves subacutely, up to 3 weeks, although once started, the deterioration may be rapid. Prompt recognition of the condition and early decompression are essential.

Other frequent causes of injury to the cords are dislocation of the head of the humerus, direct axillary trauma (stab wounds), pressure of a cervical rib or band, and supraclavicular compression during anesthesia. All cords of the plexus may be injured, or they may be affected in various combinations.

**Costoclavicular (Thoracic Outlet) Syndrome**  
This is discussed in Chap. 11 (page 186).

**Brachial Neuritis, Brachial Plexitis (Neuralgic Amyotrophy, Parsonage-Turner Syndrome)**  
This illness, of obscure nature, may develop abruptly in an otherwise healthy individual; it may also complicate an infection, an injection of vaccine or antibiotic, childbirth, surgical procedures of any type, or the use of heroin. Magee and DeJong in 1960 and Tsairis and coworkers in 1972 reported large series of cases and amplified a well-known clinical picture that the clinicians had observed repeatedly and called acute brachial neuritis. The term **neuralgic amyotrophy** was applied to this symptom complex by Parsonage and Turner, who wrote extensively on the subject. Their term for the condition is not entirely inappropriate, since the clinical and EMG findings suggest a lesion of the peripheral nerves of the shoulder girdle and upper arm rather than the cords of the plexus. Actually, the exact site of the pathologic changes has not been established. Our patients have nearly all been adults ranging from 20 to 65 years of age. Males may be slightly more susceptible.

Beginning as an ache or deep burning in and around the shoulder, centered over the deltoid, at the root of the neck or base of the skull, and suspected at first of being only a “wry” neck, or neck muscle strain, the pain rapidly becomes more severe. The onset can be remarkably abrupt and occasionally awakens the patient from sleep. It is made worse by movements that involve the muscles in the region, and the patient searches for a comfortable position. Often, narcotics are required to suppress the pain. After a period of 1 to 10 days there is a rapid development of muscular weakness and, thereafter, sensory and reflex impairment. With the development of weakness, the pain begins to subside. In a few cases, the neurologic disorder occurs with little or no antecedent pain. Possibly in some there is pain that is not followed by demonstrable weakness. A small proportion of cases are bilateral at the outset, or the opposite side is affected in rapid sequence.

Unlike restricted radicular lesions, which almost never cause complete paralysis of a muscle, certain muscles involved in brachial neuritis—such as the serratus anterior, deltoid, biceps, or triceps—may be totally or almost totally paralyzed, sometimes in isolation (see later). Rarely are all the muscles of the arm involved (4 of 99 cases of Tsairis et al.). Most of the neurologic deficits in our cases have been localized around the shoulder and upper arm; only rarely has the hand been affected predominantly. Either the biceps or triceps reflex may be abolished. In a few of our cases there has been an additional median, radial, anterior or posterior intersosseous nerve palsy that can be detected and isolated by EMG to a site distal to the plexus (see later). Such patients usually have no fever, leukocytosis, or increased sedimentation rate. Occasionally there is a mild pleocytosis (10 to 50 white blood cells per cubic millimeter) and slightly increased protein in the CSF but most cases have a normal formula and sampling of CSF is not necessary for diagnosis.

Recovery of paralysis and restoration of sensation are usually complete in a matter of 6 to 12 weeks but sometimes not for a year or longer. In only about 10 percent of cases is there residual weakness and wasting of the affected muscles, and a similar number have had a recurrence some time later on the same or the opposite side. A number of our elderly patients with this condition have had little recovery of motor function in over 5 years.

Motor nerve conduction becomes impaired in 7 to 10 days as described earlier. The lesions are presumably of axonal type, and electrophysiologic features of denervation follow. A small proportion of cases are bilateral, usually sequentially, rather than simultaneously, and recurrences have been reported.

There are almost certainly highly restricted forms that affect only one or two nerves of the brachial plexus as mentioned earlier. The most common of these is an isolated palsy of the serratus anterior (long thoracic nerve). The suprascapular, axillary, posterior intersosseus, and phrenic nerves are other common sites of solitary neuritis; pain is common in the region of the axilla or shoulder but it is probable that the same disorder occurs in a painless fashion. In the case of a unilateral phrenic nerve paralysis, there is mild dyspnea on exertion and one hemidiaphragm is found to be elevated on the chest film. When the process is not progressive and no mediastinal lesion can be detected, a phrenic palsy can be assumed to fall into this idiopathic category.

Duchowny and colleagues have described a patient in whom a typical brachial neuritis occurred as part of a febrile illness that proved to be due to CMV infection, and the same has been observed rarely in patients with AIDS. A few outbreaks of brachial neuritis have been recorded and prompted the suggestion that the Coxsackie virus is the cause. Whether Lyme infection can cause brachial neuritis is unsettled but we believe we have seen at least one instance, probably more of a cervical radiculopathy; there was a pleocytosis in the CSF. The therapeutic use of interleukin-2 and interferon has apparently precipitated a few cases. Formerly, when animal antisera were in common use, this entity was rather frequent, but now this is seldom seen. In the modern era it has been seen after injection of tetanus toxoid, typhoid-paratyphoid vaccine, and triple vaccine (pertussis, diphtheria, and tetanus).
Plexitis also occurs as an uncommon idiopathic complication of the postpartum state (Lederman and Wilbourn). Some of these are repetitive or bilateral and some are familial, but otherwise the plexitis has no distinguishing features from the idiopathic type of brachial neuritis. The heredofamilial variety is described later.

One must differentiate brachial plexitis from the following conditions: (1) spondylitis or ruptured disc with root involvement, particularly the C5 and C6 roots, in which paralysis is rarely as severe as it is in plexitis; (2) brachialgia from burstsis, labral tear, or “rotator cuff” syndrome; (3) polymyalgia rheumatica; (4) entrapment neuropathies, particularly of the subcapsular or dorsal scapular nerve; (5) carcinomatous plexopathy; (6) radiation plexopathy; and, rarely (7) sarcoid and other granulomatous infiltrations. Dissection of the vertebral artery dissection may rarely simulate the pain and weakness of brachial neuritis (Berrier et al). The special case of plexopathy in patients with a genetic proclivity to pressure palsies is discussed below.

Pathologic data are sparse, but Suarez and coworkers have reported collections of intense mononuclear inflammation in fascicles of the plexus obtained by biopsy. Perivascular lymphocytes were found in the endoneurial space and, less so, in the epineurium. The disease has not been reproduced in the experimental animal. Therapy is purely symptomatic, but we have often embarked on a course of steroids and, in a few cases, other immunosuppressants when the illness continued to advance over many weeks. Corticosteroids have a beneficial effect on pain and have also been successful in some cases of lumbosacral plexitis for which reason this medication is favored by Suarez and colleagues.

Heredofamilial Brachial Plexopathy (Heredity Neuralgic Amyotrophy, HNA) Rarely, an acute and painful recurrent brachial neuropathy occurs in a familial pattern. The inheritance is autosomal dominant, and the attacks, which are painless, occur most commonly in the second and third decades of life. The authors have observed this syndrome in three generations of a family, some members having had three to five attacks at ages ranging from 3 to 45 years. Lower cranial nerve involvement and mononeuropathies in other limbs were conjoined in some instances (see Taylor). Attacks may be spontaneous or precipitated by compression, slight stretching, or minor trauma in the region of the plexus. In one family, attacks have been triggered by events that activate the immune system (fevers, infections, surgical procedures). In several such families, there are subtle characteristic facial features including narrowed and horizontally positioned eyes and a long nasal bridge (Modigliani face). Cleft palate and unusual skin folds and creases have been observed in other kindreds (Jeannot et al).

The clinical course is usually benign with good recovery of each episode but residual deficits may accumulate after recurrent attacks. We have also had experience with the contemporaneous onset of brachial plexitis in an adult brother and sister who shared the same household but had no family history of a similar problem. A shared exposure to viral or environmental agents was suspected. In Dutch families affected by the disease, Alfen and colleagues point out that some patients experience a more chronic and undulating course rather than discrete attacks.

Madrid and Bradley have examined the sural nerves from two patients with familial recurrent brachial neuropathy. In teased single nerve fibers, they found sausage-like segments of thickened myelin and redundant loops of myelin with secondary constriction of the axon. In addition, nerve fibers showed a considerable degree of segmental demyelination and remyelination. They called this aberration of myelin formation “tomacular” neuropathy (from to-

maculum, “sausage”). These changes were not observed in the sural nerve of a sporadic case of recurrent acute brachial plexus neuropathy but they are now appreciated as relatively nonspecific.

The genetic basis for this is not established precisely but genetic linkage studies map the disease to human chromosome 17q25 in many families. Another cause of recurrent brachial palsy, or of derivative syndromes involving nerves in the arms, is hereditary neuropathy with pressure palsies (HNPP) discussed in the earlier section on inherited neuropathies. As commented there, the gene defect is also on chromosome 17, but it is not the one associated with familial brachial neuritis (see Chance et al). Some confusion has arisen because CMT1A, HNPP, and the familial brachial palsy disease all have chromosome 17 defects. Pressure palsies in HNPP are painless, and there is usually an underlying and slowly advancing polyneuropathy. In some families, such as the one reported by Thomas and Ormerod, the distinction between HNA and HNPP was difficult since the recurrent brachial plexopathies were painful (consistent with the former) but there was also a painless multifocal sensory neuropathy (consistent with the latter).

Brachial Neuropathy following Radiation Therapy This is usually a complication of irradiation of the axilla for carcinoma of the breast. Stoll and Andrews studied a group of 117 such patients who were treated with high-voltage, small-field therapy and had received either 6300 or 5775 cGy in divided doses. Of those receiving the larger dose, 73 percent developed weakness and sensory loss in the hand and fingers between 4 and 30 months after treatment, most of them after 12 months. In one autopsied case, the brachial plexus was enshrouded in dense fibrous tissue; distal to this zone, both myelin and axons had disappeared (secondary to Wallerian degeneration), presumably as a result of entrapment of nerves in fibrous tissue; possibly a vascular factor was also operative.

Kori and coworkers, who analyzed the brachial plexus lesions in 100 patients with cancer, also found that doses exceeding 6000 cGy were associated with radiation damage. Usually the upper plexus was involved and was associated with a painless lymphedema. In patients who received lower doses, the development of brachial plexopathy usually indicated tumor infiltration; these lesions affected the lower plexus more than the upper; they were often painful and accompanied by a Horner syndrome (see also Lederman and Wilbourn). Rarely, radiation may give rise, many years later, to a malignant tumor of nerve or the surrounding connective tissue, a sarcoma in one case familiar to us. Myokymic discharges and fasciculations are particularly suggestive of radiation damage.

Herpes Zoster Plexitis, Neuritis, and Ganglionitis (See Chap. 33) This organism is perhaps the best-defined infectious cause of the listed syndromes, but its identification is usually obvious. Cases are known in which radicular pain precedes the eruption by many days or in which shingles do not appear, thereby simulating a herniated disc (Zoster sine herpete). These conditions are discussed with the other viral infections of the nervous system.

Musculocutaneous Nerve

The origin of this nerve is from the fifth and sixth cervical roots. It is a branch of the lateral cord of the brachial plexus and innervates the biceps, brachialis, and coracobrachialis muscles. Lesions of the nerve result in wasting of these muscles and weakness of flexion of the supinated forearm. Sensation may be impaired along the radial and volar aspects of the forearm (lateral cutaneous nerve). Isolated lesions of this nerve are usually the result of fracture of the humerus.

Radial Nerve

This nerve is derived from the sixth to eighth (mainly the seventh) cervical roots and is the distal extension of the posterior cord of the brachial plexus. It innervates the triceps, brachioradialis, and supinator muscles and continues below the elbow as the posterior interosseous nerve, which innervates the extensor muscles of the wrist and fingers, the abductor of the thumb, and the extensors of the fingers at both joints. A complete proximal radial nerve lesion results in paralysis of extension of the elbow, flexion of the elbow with the forearm midway between pronation and supination (due to paralysis of the brachioradialis muscle), supination of the forearm, extension of the wrist and fingers, and extension and abduction of the thumb in the plane of the palm. If the lesion is confined to the posterior interosseous nerve, only the extensors of the wrist and fingers are affected. Sensation is impaired over the posterior aspects of the forearm and over a small area on the radial aspect of the dorsal of the hand.

The radial nerve may be compressed in the axilla (“crutch palsy”) but more frequently at a lower point, where the nerve winds around the humerus (see Table 46-8); pressure palsies incurred during an alcoholic stupor and fractures of the humerus commonly injure the nerve at the site of injury. It is susceptible to lead intoxication and is frequently involved as part of a neuralgic amyotrophy.

Median Nerve

This nerve originates from the fifth cervical to the first thoracic roots but mainly from the sixth cervical root and is formed by the union of the medial and lateral cords of the brachial plexus. It innervates the pronators of the forearm, long finger flexors, and abductor and opponens muscles of the thumb and is a sensory nerve to the palmar aspect of the hand. Complete interruption of the median nerve results in inability to pronate the forearm or flex the hand in a radial direction, paralysis of flexion of the index finger and terminal phalanx of the thumb, weakness of flexion of the remaining fingers, weakness of opposition and abduction of the thumb in the plane at a right angle to the palm (abductor and flexor pollicis brevis), and sensory impairment over the radial two-thirds of the palm and dorsum of the distal phalanges of the index and third fingers. The nerve may be injured in the axilla by dislocation of the shoulder and in any part of its course by stab, gunshot, or other types of wounds. Incomplete lesions of the median nerve between the axilla and wrist may result in causalgia (see further on).

Carpal Tunnel Syndrome

Compression of the median nerve at the wrist (carpal tunnel syndrome) is the most common disorder affecting the median nerve and the most frequent nerve entrapment syndrome. This is usually due to excessive use of the hands and occupational exposure to repeated trauma. Infiltration of the transverse carpal ligament with amyloid (as occurs in multiple mye-
loma) or thickening of connective tissue in rheumatoid arthritis, acromegaly, amyloidosis, mucopolysaccharidosis, and hypothyroidism are less commonly identified causes. It is not uncommon for the condition to make its appearance during pregnancy. In elderly individuals, the cause of the carpal tunnel syndrome is often not apparent. According to Kremer and colleagues, it was McArdle, in 1949, who first suggested that the cause of this syndrome was a compression of the median nerve at the wrist and that the symptoms would be relieved by division of the flexor retinaculum forming the ventral wall of the carpal tunnel.

Dysesthesias and pain in the fingers, referred to for many years as “acroparesthesiae” and attributed to cervical ribs, came to be recognized as a syndrome of median nerve compression only in the early 1950s. The syndrome is essentially a sensory one; the loss or impairment of superficial sensation affects the palmar aspect of the thumb, and the index, and middle fingers (especially the index finger) and may or may not split the ring finger (splitting does not occur with a plexus or root lesion). The paresthesias are characteristically worse during the night. As pointed out in Chap. 11, the pain in carpal tunnel syndrome may radiate into the forearm and even into the region of the biceps and rarely to the shoulder. Weakness and atrophy of the abductor pollicis brevis and other median-innervated muscles occur in only the most advanced cases of compression. Electrophysiologic testing confirms the diagnosis by demonstrating prolonged sensory conduction across the wrist and explains cases in which operation has failed (see also the review by Stevens).

Several provocative tests are useful. The Phalen maneuver consists of hyperflexion of the wrist for 30 to 60 s—usually performed by opposing the outer surfaces of the hands with the wrists flexed. The Tinel sign is elicited by lightly tapping the ulnar aspect of the wrist at the transverse carpal ligament (distal to the first wrist crease). Both of these tests are meant to elicit pain or paresthesias over the digits innervated by the median nerve. The sensitivity of these tests is close to 50 percent but their specificity is considerably higher. Other tests involving prolonged pressure over the median nerve have been devised but they are of uncertain value, e.g., Durken’s test of the Phelan maneuver combined with digital compression of the nerve.

Treatment Surgical division of the carpal ligament with decompression of the nerve is curative but is required only in severe and protracted cases. Splinting of the wrist, to avoid flexion, almost always relieves the discomfort but denies the patient the full use of the hand for some time. It is a useful temporizing measure, however, as is the injection of hydrocortisone into the carpal tunnel. Studies of oral corticosteroids have given conflicting results. Treatment of an underlying condition such as arthritis, hypothyroidism, possibly diabetes, is often helpful. Some patients have benefited, paradoxically, from the stopping of corticosteroids or estrogen. Also, some practitioners favor the use of nonsteroid anti-inflammatory medication but we have been generally unimpressed with the results. Most often, splinting and local steroid injections are very satisfactory in the short-term, especially if the symptoms are of recent onset.

Another less common site of compression of the median nerve is at the elbow, where the nerve passes between the two heads of the pronator teres, or just above that point behind the bicipital aponeurosis. It gives rise to the pronator syndrome, in which forceful pronation of the forearm produces an aching pain (see Table 46-8). There is weakness of the abductor pollicis brevis and opponens muscles and numbness of the first three digits and palm.

Ulnar Nerve This nerve is derived from the eighth cervical and first thoracic roots. It innervates the ulnar flexor of the wrist, the ulnar half of the deep finger flexors, the adductors and abductors of the fingers, the adductor of the thumb, the third and fourth lumbricals, and muscles of the hypothenar eminence. Complete ulnar paralysis is manifest by a characteristic claw hand deformity; wasting of the small hand muscles results in hyperextension of the fingers at the metacarpophalangeal joints and flexion at the interphalangeal joints. The flexion deformity is most pronounced in the fourth and fifth fingers, since the lumbrical muscles of the second and third fingers, supplied by the median nerve, counteract the deformity. Sensory loss occurs over the fifth finger, the ulnar aspect of the fourth finger, and the ulnar border of the palm.

The ulnar nerve is vulnerable to pressure in the axilla from the use of crutches, but it is most commonly injured at the elbow by fracture or dislocation involving the joint. Delayed (“tardive”) ulnar palsy may occur many months or years after an injury to the elbow that had resulted in a cubitus valgus deformity of the joint. Because of the deformity, the nerve is stretched in its groove over the ulnar condyle, and its superficial location renders it vulnerable to compression. A shallow ulnar groove, quite apart from abnormalities of the elbow joint, may expose the nerve to compressive injury. Anterior transposition of the ulnar nerve is a simple and effective form of treatment for these types of ulnar palsy. Compression of the nerve may occur just distal to the medial epicondyle, where it runs beneath the aponeurosis of the flexor carpi ulnaris (cubital tunnel). Flexion at the elbow causes a narrowing of the tunnel and constriction of the nerve. This type of ulnar palsy is treated by incising the aponeurotic arch between the olecranon and medial epicondyle. Yet another site of ulnar nerve compression is in the ulnar tunnel, at the wrist. Prolonged pressure on the ulnar part of the palm may result in damage to the deep palmar branch of the ulnar nerve, causing weakness of small hand muscles but no sensory loss. This site is most often implicated in patients who hold tools or implements tightly in the hand for long periods (we have seen it in machinists and professional cake decorators). The lesion is localizable by nerve conduction studies.

A characteristic syndrome of burning pain and associated symptoms (causalgia) may follow incomplete lesions of the ulnar nerve (or other major nerves of the limbs) and is described further on.

Lumbosacral Plexus and Crural Neuropathies

The twelfth thoracic, first to fifth lumbar, and first, second, and third sacral spinal nerve roots compose the lumbosacral plexuses and innervate the muscles of the lower extremities (Fig. 46-6 and Table 46-1). The following are the common plexus and crural nerve palsy.

Lumbosacral Plexus Lesions Extending as it does from the upper lumbar area to the lower sacrum and passing near several lower abdominal and pelvic organs, this plexus is subject to a number of special injuries and diseases, most of them secondary. The cause of involvement may be difficult to ascertain because the primary disease is often not within reach of the palpating fingers, either from the abdominal side or through the anus and vagina; even refined radiologic techniques may not reveal it. Diagnosis involves exclusion of spinal root (cauda equina) lesions by EMG, examination of CSF, computed tomography (CT) myelography, and
MRI. The clinical findings help to focus studies on the appropriate part of the lumbosacral plexus.

The main effects of upper lumbar plexus lesions are weakness of flexion and adduction of the thigh and extension of the leg, with sensory loss over the anterior thigh and leg; these effects must be distinguished from the symptoms and signs of femoral neuropathy (see later). Lower plexus lesions weaken the posterior thigh, leg, and foot muscles and abolish sensation over the first and second sacral segments (sometimes the lower sacral segments also). Lesions of the entire plexus, which occur infrequently, cause a weakness or paralysis of all leg muscles, with atrophy, areflexia, anesthesia from the toes to the perianal region and autonomic loss with warm, dry skin. Usually there is edema of the leg as well.

The types of lesions that involve the lumbosacral plexus are rather different from those affecting the brachial plexus. Trauma is a rarity except with massive pelvic, spinal, and abdominal injuries because the plexus is so well protected. Occasionally a pelvic fracture will damage the sciatic nerve as it issues from the plexus. In contrast, some part of the plexus may be damaged during surgical procedures on abdominal and pelvic organs, often for reasons that may not be entirely clear. For example, hysterectomy has on a number of occasions led to neurologic consultation in our hospitals because of numbness and weakness of the anterior thigh. Either the cords of the upper part of the plexus or the femoral nerve was compressed by retraction against the psoas muscle or, in vaginal hysterectomy (when thighs are flexed, abducted, and externally rotated), the femoral nerve was compressed against the inguinal ligament. A similar type of injury may be associated with childbirth. Lumbar sympathectomy has also been associated with upper plexus lesions, of which the most disabling sequela are burning pain and hypersensitivity of the anterior thigh. Appendectomy, pelvic explorations, and hernial repair may injure branches of the upper plexus (ilioinguinal, iliohypogastric, and genitofemoral nerves), with severe pain and slight sensory loss in the distribution of one of these nerves. The pain may last for months or a year or more.

The lumbosacral plexus may be compressed by an aortic atherosclerotic aneurysm. Usually there is pain that radiates to the hip, the anterior thigh, and occasionally the flank. Slight weakness in hip flexion and altered sensation over the anterior thigh are found on examination. Plexus involvement with tumors is commonplace and at times presents special difficulties in diagnosis. Carcinoma of either the cervix or prostate may seed itself along the perineurial lymphatics and cause pain in the groin, thigh, knee, or back without much in the way of sensory, motor, or reflex loss. The pain is more often unilateral than bilateral. The CSF and spinal canal (by MRI) are normal. Testicular, uterine, ovarian, and colonic tumors or retroperitoneal lymphomas, by extending along the paravertebral gutter, implicate various parts of the lumbosacral plexus. Instances of endometriosis that involve the plexus have also been reported. The neurologic symptoms are projected at a distance in the leg and may or may not be confined to the territory of any one nerve. Pelvic and rectal examinations may be negative, and CT scanning and MRI may be necessary to show such lesions. If all these examinations are negative, exploratory laparotomy may have to be undertaken.

In cancer patients, it is sometimes difficult to distinguish the effects of radiation on the lumbosacral plexus from those of metastatic tumor, as is the case in relation to the brachial plexus. Again, the earliest symptom in metastatic lumbosacral plexopathy is usually pain, whereas in radiation plexopathy it is weakness (Thomas et al); the same as pertains in the brachial plexus. Plexopathy from metastatic tumor is usually unilateral and detectable by CT scanning; radiation plexopathy was usually bilateral and not evident in...
CT scans. Fasciculations and myokymia are more likely to be seen in patients with radiation plexopathy, which seemingly occurs more frequently in patients with diabetic neuropathy.

Reference has already been made to femoral nerve injury during parturition, but other *puerperal complications* are also observed. Back pain in the latter part of pregnancy is common, but there are rare instances in which the patient complains of severe pain in the back of one or both thighs during labor and after delivery has numbness and weakness of the leg muscles, with diminished ankle jerks. *Parturitional lumboSacral Plexus Injuries* occur with a frequency of 1 per 2000 deliveries. This type of plexus injury is usually unilateral and is manifest by pain in the thigh and leg and symptoms and signs of involvement of the superior gluteal and sciatic nerves (Feasby et al). The attribution of these symptoms to pressure of the fetal head on the sacral plexus(es) is conjectural. A limited plexopathy, occurring after difficult vaginal delivery, mainly impairs sensation in the perineum and sphincteric function (Ismael et al). The perineal muscles may show signs of denervation. Protrusion of an intervertebral disc may also occur during delivery.

**Idiopathic LumbarSacral Plexitis** In addition to a diabetic type, an idiopathic *neuropathic amyotrophy or lumbarSacral plexitis*, analogous to the brachial variety, is observed from time to time. Bradley and coworkers have recorded such cases. After causing widespread unilateral or bilateral sensory, motor, and reflex changes in a leg, lumbarSacral plexitis may leave the patient with dysesthesias as troublesome as those that follow herpes zoster (which may also occur at this level). Some patients have had an exploration of the cauda equina (for ruptured disc), even though loss of sweating and warmth of the feet should have indicated interruption of autonomic fibers by lesions in peripheral nerves. (Lesions that are confined to nerve roots spare autonomic functions.) The sedimentation rate may be elevated. Immunosuppressant drugs were possibly beneficial in 4 of 6 cases (Bradley et al). Sarcoïdosis is another cause and may be responsive to corticosteroids.

*Diabetic amyotrophy,* due to involvement of the lumbar plexus, has a vascular origin, probably inflammatory as discussed in an earlier section (page 1135), and there are also nondiabetic vascular lesions that give rise to identical lumbar and upper leg pain and weakness in proximal muscles. The plexus lesions of polyarteritis nodosa, unilateral or bilateral, may also be manifest as a mononeuropathy multiplex. Mononeuropathy multiplex in diabetic patients is more frequent in our experience when there is an associated occlusive vascular disease of the lower extremities. Diabetic mononeuropathy multiplex is discussed in an earlier part of this chapter and protruded intervertebral disc syndromes are described in Chap. 11.

**Lateral Cutaneous Nerve of the Thigh** This is a sensory nerve that originates from the second and third lumbar roots and supplies the anterolateral aspect of the thigh, from the level of the inguinal ligament almost to the knee. The nerve penetrates the psoas muscle, crosses the iliacus, and passes into the thigh by coursing between the attachments of the lateral part of the inguinal ligament to just anterior to the anterior superior iliac spine. Compression (entrapment) may occur at the point where it passes between the two prongs of attachment of the inguinal ligament.

Compression of the nerve results in uncomfortable paresthesias and sensory impairment in its cutaneous distribution, a common condition known as *meralgia paresthetica* (*meros*, “thigh”). Usually numbness and mild sensitivity of the skin are the only symptoms, but occasionally there is a persistent distressing burning pain. Perception of touch and pinprick are reduced in the territory of the nerve; there is no weakness of the quadriceps or diminution of the knee jerk. The symptoms are characteristically worsened in certain positions and after prolonged standing or walking. Occasionally, for an obese person, sitting is the most uncomfortable position. Obesity, pregnancy, and diabetes mellitus may be contributory factors. Most often the neuropathy is unilateral; Ecker and Woltman found only 20 percent of their cases to be bilateral.

Most of our patients with meralgia paresthetica request no treatment once they learn of its benign character. Weight loss and adjustment of restrictive clothing or correction of habitual postures that might compress the nerve are sometimes helpful. A few with the most painful symptoms have demanded a neurectomy or section of the nerve, but it is always wise to perform a lidocaine block first, so that the patient can decide whether the persistent numbness is preferable. In one specimen of nerve obtained at operation, we found a discrete traumatic neuroma. Hydrocortisone injections at the point of entrapment may have helped in a few cases.

**Obturator Nerve** This nerve arises from the third and fourth and to a lesser extent the second lumbar roots. It supplies the adductors of the thigh and contributes to the innervation of the internal and external rotators. The adductors have the added function of flexing the hip. The nerve may be injured by the fetal head or forceps during the course of a difficult labor or compressed by an obturator hernia. Rarely, it is affected with diabetes, polyarteritis nodosa, and osteitis pubis and by retroperitoneal spread of carcinoma of the cervix, uterus, and other tumors (Rogers et al).

**Femoral Nerve** This nerve is formed from the second, third, and fourth lumbar roots. Within the pelvis it passes along the lateral border of the psoas muscle and enters the thigh beneath Poupart’s ligament, lateral to the femoral artery. Branches arising within the pelvis supply the iliacus and psoas muscles. Just below Poupart’s ligament the nerve splits into anterior and posterior divisions. The former supplies the pectineus and sartorius muscles and carries sensation from the anteromedial surface of the thigh; the posterior division provides the motor innervation to the quadriceps and the cutaneous innervation to the medial side of the leg from the knee to the internal malleolus.

Following injury to the femoral nerve, there is weakness of extension of the lower leg, wasting of the quadriceps muscle, and failure of fixation of the knee. The knee jerk is abolished. If the nerve is injured proximal to the origin of the branches to the iliacus and psoas muscles, there is weakness of hip flexion. The adductor of the thigh (innervated by the obturator nerve) is spared, distinguishing femoral neuropathy from an L3 radiculopathy.

The most common cause of femoral neuropathy is diabetes. The nerve may also be involved by pelvic tumors. Not uncommon is injury of the nerve during pelvic operations. Usually this is the result of improper placement of retractors, which may compress the nerve directly or indirectly by undue pressure on the psoas muscle. Bleeding into the iliacus muscle or the retroperitoneum, observed in patients receiving anticoagulants and in hemophilia patients, is a relatively common cause of isolated femoral neuropathy (Goodfellow et al). The presenting symptom of iliacus hernia is pain in the groin spreading to the lumbar region or thigh, in response to which the patient assumes a characteristic posture of flexion and lateral rotation of the hip. A palpable mass in the iliac fossa and the signs of femoral nerve compression (quadriceps weakness and loss of knee jerk) follow in a day or two. Infarction
of the nerve may occur in the course of diabetes mellitus and polyarteritis nodosa. Not infrequently acute femoral neuropathy is of indeterminate cause.

Sciatic Nerve  This nerve is derived from the fourth and fifth lumbar and first and second sacral roots, for which reason a ruptured disc at any of these levels may simulate sciatic neuropathy (sciatica). The sciatic nerve supplies motor innervation to the hamstring muscles and all the muscles below the knee through its two divisions, the tibial and peroneal nerves (see later); the sciatic nerve conveys sensory impulses from the posterior aspect of the thigh, the posterior and lateral aspects of the leg, and the entire sole. In complete sciatic paralysis, the knee cannot be flexed and all muscles below the knee are paralyzed. Weakness of gluteal muscles and pain in the buttock and posterior thigh point to nerve involvement in the pelvis. Lesions beyond the sciatic notch spare the gluteal muscles but not the hamstrings. Partial compressive lesions are more common and tend to involve peroneal-innervated muscles more than tibial ones, giving the impression of a peroneal palsy.

As mentioned, rupture of one of the lower lumbar intervertebral discs is perhaps the most common cause of sciatica, although it does not directly involve the sciatic nerve. The associated motor and sensory findings allow localization of the root compression (L4-5 disc compressing L5 root: pain in posterolateral thigh and leg with numbness over the inner foot and weakness of dorsiflexion of the foot and toes; L5-S1 disc compressing S1 root: pain in posterior thigh and leg, numbness of lateral foot, weakness of foot dorsiflexion and loss of ankle jerk) as discussed in Chap. 11.

The sciatic nerve is commonly injured by fractures of the pelvis or femur, fracture/dislocation of the hip, gunshot wounds of the buttock and thigh, and the injection of toxic substances into the lower gluteal region. Total hip arthroplasty is another common cause. Tumors of the pelvis (sarcomas, lipomas) or gluteal region may compress the nerve. Sitting for a long period with legs flexed and abducted (lotus position) under the influence of narcotics or barbiturates or lying flat on a hard surface in a sustained stupor may severely injure one or both sciatic nerves or branches thereof. The nerve may be involved by neurofibromas and infections and may severely injure one or both sciatic nerves or branches thereof. The nerve may be involved by neurofibromas and infections and by ischemic necrosis in diabetes mellitus and polyarteritis nodosa. Cryptogenic forms also occur and are actually more frequent than those of identifiable cause. Partial lesions of the sciatic nerve occasionally result in causalgia (see further on).

The common Morton neuromas cause interdigital or intermetatarsal pain and can be detected by MRI. It is subject to surgical section. Also mentioned here is the distressingly painful compression of the plantar branches of the sciatic nerve.

Common Peroneal Nerve  Just above the popliteal fossa the sciatic nerve divides into the tibial nerve (medial, or internal, popliteal nerve) and the common peroneal nerve (lateral, or external, popliteal nerve). The latter swings around the head of the fibula to the anterior aspect of the leg, giving off the superficial peroneal nerve which provides musculocutaneous branches (to the peroneal muscles) and to the deep peroneal nerve (formerly called anterior tibial nerve). Branches of the latter supply the dorsiflexors of the foot and toes (anterior tibialis, extensor digitorum longus and brevies, and extensor hallucis longus muscles) and carry sensory fibers from the dorsum of the foot and lateral aspect of the lower half of the leg. There was weakness of dorsiflexion of the foot in all of the 116 cases of common peroneal neuropathy reported byKatirji and Wilbourn, and numbness of the dorsum of the foot was present in most cases. Weakness of eversion of the foot is usually demonstrable; inversion, a function of the L-5 root and the tibial nerve, is spared and the ankle jerk is normal, unless affected by another process. Foot eversion must be tested with the ankle passively dorsiflexed to 90 degrees. Pain is variable; it was quite severe in a few of our patients.

Pressure during an operation or sleep or from tight plaster casts, obstetric stirrups, habitual and prolonged crossing of the legs while seated, and tight knee boots are the most frequent causes of injury to the common peroneal nerve. The point of compression of the nerve is where it passes over the head of the fibula. Emaciation in patients with cancer or AIDS increases the incidence of these types of compressive injury. The nerve may also be affected in diabetic neuropathy and injured by fractures of the upper end of the fibula. A Baker cyst, which consists of inflamed synovium extending into the retropopliteal space may compress the nerve, and it may be damaged by muscle swelling or small hematomas behind the knee in asthenic athletes. The prognosis is generally good in cases of partial paralysis.

Tibial Nerve  This, the other of the two divisions of the sciatic nerve (it divides in the popliteal fossa), supplies all of the calf muscles—i.e., the plantar flexors and invertors of the foot and toes—after which it continues as the posterior tibial nerve. This nerve passes through the tarsal tunnel, an osseofibrous channel that runs along the medial aspect of the calcaneus and is roofed by the flexor retinaculum. The tunnel also contains the tendons of the tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles and the vessels to the foot. The posterior tibial nerve terminates under the flexor retinaculum and divides into medial and lateral plantar nerves (supplying the small muscles of the foot).

Complete interruption of the tibial nerve results in a calcanoevalgus deformity of the foot, which can no longer be plantarflexed and inverted. There is loss of sensation over the plantar aspect of the foot.

The posterior tibial nerve may be compressed in the tarsal tunnel (an entrapment syndrome as discussed later) by thickening of the tendon sheaths or the adjacent connective tissues or by osteoarthritic changes. Tingling pain and burning over the sole of the foot develop after standing or walking for a long time. Pain in the ankle or foot is added in some cases and the pain may be referred proximally along the sciatic nerve. Pressure over the nerve in the inferior malleolar region produces pain, which radiates to the terminal distributions of the nerve. Usually there is no motor deficit. Relief is obtained by severing the flexor retinaculum.

Entrapment Neuropathies

Reference has been made in several places in the preceding pages to the main entrapment neuropathies. A nerve passing through a tight canal is trapped and subjected to constant movement or pressure, forces not applicable to nerves elsewhere. The epineurium and perineurium become greatly thickened, stranding the nerve, with the additional possibility of demyelination. Function is gradually impaired, sensory more than motor, and the symptoms fluctuate with activity and rest. The most frequently compressed nerves are the median, ulnar, peroneal, tibial, and plantar in approximately that order. It is well to keep in mind the systemic processes that enhance pressure palsy or by infiltration of the nerve or surrounding
Causalgia and Reflex Sympathetic Dystrophy

One unfortunate result of partial injury of a peripheral nerve is the delayed appearance of severe pain roughly in the distribution of the affected nerve. This complex problem, which consists of burning pain termed causalgia and associated local trophic and autonomic changes that are subsumed under the term reflex sympathetic dystrophy, are discussed further in Chap. 8 in the context of other pain syndromes.

Traumatic Interruption of Nerves

The management of such lesions is best delegated to specialized neurosurgeons, but several aspects involve the neurologist. Surgical advances have allowed the successful apposition of severed nerve ends. The current recommendations are that end-to-end suturing of the stumps within 72 h should repair a sharp and clean division. In cases where the nerve is found on exploration to be bluntly severed with ragged ends, most surgeons recommend tacking the free ends to adjacent connective tissue planes and attempting repair in 2 to 4 weeks. The majorities of injuries, however, are blunt and retain some continuity of the nerve. If such continuity across the traumatized region can be demonstrated by electrophysiologic examination, operation is not necessary. In the absence of improvement in the clinical and electrophysiologic features after several months (up to 6 months for plexus lesions), surgical repair may facilitate limited healing.

CHAPTER 46  DISEASES OF THE PERIPHERAL NERVES

CHAPTER 47
DISEASES OF THE CRANIAL NERVES

The cranial nerves are susceptible to a number of special diseases, some of which never affect the spinal peripheral nerves. For this reason alone they deserve to be considered separately. Certain of the cranial nerves and their disorders have already been discussed: namely, disorders of olfaction, in Chap. 12; of vision and extraocular muscles, in Chaps. 13 and 14; of cochllear and vestibular function, in Chap. 15; and craniofacial pain in Chap. 10. There remain to be described the disorders of the facial (VII) nerve and of the lower cranial nerves (IX to XII), as well as certain aspects of disordered trigeminal (V) nerve function. These are considered here.

The Fifth, or Trigeminal, Nerve

Anatomic Considerations  The fifth nerve (Fig. 47-1) is a mixed sensory and motor nerve. It conducts sensory impulses from the greater part of the face and head; from the mucous membranes of the nose, mouth, and paranasal sinuses; and from the cornea and conjunctiva. It also innervates the dura of the anterior and middle cranial fossae. The cell bodies of the sensory part of the nerve lie in the gasserian, or semilunar, ganglion. This, the largest sensory ganglion in humans, lies in the medial part of the middle cranial fossa at the base of the cranium. The central axons of the ganglion cells form the sensory root. These fibers, on entering the mid pons, divide into short ascending and long descending branches. The former are concerned mainly with tactile and light pressure sense and synapse with second-order neurons in the principal sensory nucleus. Proprioceptive afferents from facial muscles and the masticator terminate in the mesencephalic nucleus. The fibers that mediate pain and temperature sensation do not end in these nuclei but form the unique anatomy of the long descending branches of the spinal trigeminal tract. The latter pathway, which contains both facilitatory and inhibitory fibers, together with its nucleus, extends from the junction of the pons and medulla to the uppermost segments (C2 or C3) of the spinal cord (as evidenced by the relief of facial pain after bulbary medullary tractotomy). The spinal nucleus is a continuation of the spinal tract of Lissauer and substantia gelatinosa; the main sensory nucleus is a continuation of the nucleus of the medial lemniscus. From all parts of the principal trigeminal sensory and spinal nuclei, second-order fibers cross to the opposite side and ascend to the thalamus. They come to lie in the most medial part of the spinoholamic tract and lateral part of the medial lemniscus. These systems of fibers are called the trigeminothalamic tract. In addition, the secondary trigeminal neurons project to the facial and hypoglossal nuclei bilaterally, the salivatory nuclei, the cuneate nuclei of the upper cervical segments, and other cranial nerve nuclei. The main sensory and spinal trigeminal nuclei receive fibers from the reticular formation, the thalamus, the nucleus solitarius, and the sensory cortex.

The peripheral branches of the gasserian ganglion form the three sensory divisions of the nerve. The first (ophthalmic) division passes through the superior orbital fissure; the second (maxillary) division leaves the middle fossa through the foramen rotundum; and the third (mandibular), through the foramen ovale.

The motor portion of the fifth nerve, which supplies the masticator and pterygoid muscles, has its origin in the trigeminal motor nucleus in the midpons; the exiting fibers pass underneath the gasserian ganglion and become incorporated into the mandibular nerve. The masticator and pterygoid muscles are utilized in chewing and are implicated in a number of brainstem reflexes, the best known of which is the jaw jerk. Tapping the chin with the jaw muscles relaxed stimulates proprioceptive afferents that terminate in the mesencephalic nucleus of the midbrain, which sends collaterals to the motor nucleus of the fifth nerve and causes the masticators to contract. This reflex is enhanced in spastic bulbar (pseudobulbar) palsy. Another pontine reflex that utilizes afferent trigeminal sensory nerves is the blink reflex. Tapping of the brow or bridge of the nose evokes bilateral blink through activation of the orbicularis oculi muscles (facial nerve efferents). Touching the eyelids and cornea (corneal reflex) does the same.

Because of their wide anatomic distribution, complete interruption of both the motor and sensory fibers of the trigeminal nerve is rarely observed. In contrast, partial affection of the trigeminal nerve, particularly of the sensory part, is not uncommon, the main symptoms being numbness and pain. The various cranial nerve and brainstem syndromes in which the fifth nerve is involved are listed in Tables 47-1, 31-4, and 34-3, the last in relation to stroke syndromes of the brainstem.

Diseases Affecting the Fifth Nerve  A variety of diseases may affect the peripheral branches of the trigeminal nerves, the gasserian (semilunar) ganglion, and the roots (sensory and motor). These have been ably described by Hughes. The role of the nerve in the genesis of migraine is discussed in Chap. 10.

Trigeminal Neuralgia (see also page 161)  The most frequent, and at the same time the most elusive disease of the fifth nerve from the standpoint of its pathologic basis, is trigeminal neuralgia (tic douloureux), which is also discussed in Chap. 10. This condition has been known since ancient times, having been described by Arateus in the first century A.D., by John Locke in 1677, by Nicolaus Andre in 1756, and by John Fothergill in 1776 (according to Katusic et al). The overall incidence rate for both sexes combined is 4.3 per 100,000 persons per year, but it is higher for women than for men (in a ratio of 3:2) and is much higher in the elderly. The mean age of onset is 52 to 58 years for the idiopathic form and 30 to 35 years for the symptomatic forms, the latter being caused by trauma or vascular, neoplastic, and demyelinative diseases. In the last decade it has become apparent, mainly from the work of Janetta, that a proportion of cases is due to compression of trigeminal nerve rootlets by small branches of the basilar artery. This compression causes demyelination of the proximal nerve root (see Love and Coakham).

The paroxysmal nature of the facial pain, its unilaterality and tendency to involve the second and third divisions of the trigeminal nerve, an intensity that makes the patient grimace or wince (tic), the presence of an initiating or trigger point, the lack of demonstrable sensory or motor deficit, and its response in more than half
of the cases to carbamazepine, phenytoin, and other similar drugs are characteristic. The diagnosis of “idiopathic” trigeminal neuralgia and its differentiation from other forms of intermittent facial pain described below—as well as from cluster headache, dental neuralgia, temporomandibular pain, and atypical facial pain—is usually not difficult, especially if there is a trigger point and no demonstrable evidence of sensory or motor impairment. The vascular compressive form, still usually subsumed in the category of idiopathic, is difficult to diagnose without exposure at operation. The treatment of trigeminal neuralgia is considered on page 163.

In rare instances, trigeminal neuralgia is preceded or accompanied by hemifacial spasm, a combination that Cushing called tic convulsif. This may be indicative of a tumor (cholesteatoma), an aneurysmal dilatation of the basilar artery, or one of its branches, or an arteriovenous malformation that compresses both the trigeminal and facial nerves. Trigeminal neuralgia and glossopharyngeal neuralgia (pain in the tonsillar region, see page 163 and further on) may also be combined in these disease states, but these conditions are more often idiopathic.

**Trigeminal Neuropathies and Neuritis** Of the conditions that damage the branches of the trigeminal nerve, facial and cranial injuries and fractures are probably the most common but they do not often come to the attention of neurologists. The most superficial branches of the nerve—the supratrochlear, supraorbital, and infraorbital—are the ones usually involved. The sensory loss is present from the time of the injury, and partial regeneration may be attended by constant pain, often demanding nerve block or sectioning.

Of the various inflammatory and infectious diseases that affect the trigeminal nerves or ganglia, herpes zoster ranks first (pages 163 and 642). Persistent pain after herpetic infection of the fifth nerve is a serious problem, not responding well to any type of treatment. This subject is discussed in Chap. 10. *Herpes simplex virus* has been isolated from the ganglion in as many as 50 percent of routine autopsies, but in nearly all patients this virus is associated only with lesions of the skin and lips. Middle ear infections and osteomyelitis of the apex of the petrous bone may spread to the ganglion and root, also implicating the sixth cranial nerve (Gradenigo syndrome). Human immunodeficiency virus (HIV) infection has not been clearly implicated in infection of the fifth nerve (as it has in the seventh nerve), but reactivation of latent herpes zoster is seen with acquired immune deficiency syndrome (AIDS).

The trigeminal root may be compressed or invaded by intracranial meningiomas, acoustic neuromas, trigeminal neuromas (Fig. 47-2), cholesteatomas, and chordomas and by tortuous branches of the basilar artery. Sinus tumors and metastatic disease may also implicate the nerve, causing pain and a gradually progressive sensory loss. The ophthalmic division of the fifth nerve may be involved in the wall of the cavernous sinus in combination with the third, fourth, and sixth nerves by a variety of processes, including thrombosis of the cavernous sinus. Tumors of the sphenoid bone (myeloma, metastatic carcinoma, squamous cell carcinoma, and lymphoepithelioma of the nasopharynx) may involve branches of the trigeminal nerve at their foramina of entry or exit. The mandibular division may be compressed by the roots of an impacted third molar (wisdom) tooth. Several times the authors have observed numbness of the chin and lower lip (infiltration of the mental nerve) as the first indication of metastatic carcinoma of the breast and prostate and from multiple myeloma. Massey and colleagues have described 19 such cases ("numb-chin" syndrome). An unusual perineural spread of tumor from squamous cell skin cancers of the face is discussed further on, under “Multiple Cranial Nerve Palsies.”

Neurologists often encounter instances of slowly evolving unilateral or bilateral trigeminal neuropathy in which sensory impairment is confined to the territory of the trigeminal nerve, sometimes associated with pain and paresthesias and disturbances of taste. Loss of facial sensation can occur as part of a widespread sensory neuropathy that occurs as a remote effect of cancer or as part of Sjögren disease (pages 586 and 1141). More common is an association between isolated trigeminal neuropathy and immune-mediated connective tissue disease. Of 22 such cases described by Lecky and colleagues, 9 had either scleroderma or mixed connective tissue disease, and a similar number had either organ- or non-organ-specific serum autoantibodies. The symptoms may involve the other side years later. Hughes has also reported cases of trigeminal neuropathy with scleroderma, lupus erythematosus,

---

**Figure 47-1.** Scheme of the trigeminal nuclei and some of the trigeminal reflex arcs. I, principal sensory nucleus; II, Gasserian ganglion; III, mesencephalic nucleus. The trigeminal motor root fibers are shown with the motor nuclei of cranial nerves V and VII.}
and Sjögren disease. We have seen several patients with Sjögren disease in whom the trigeminal neuropathy and the associated antibodies or inflammation of the minor salivary glands were evident well before the characteristic sicca syndrome or other systemic manifestations of the disease. The condition may remain troublesome for years. Pathologic data are limited but point to an inflammatory lesion of the trigeminal ganglion or sensory root. Stilbamidine and trichloroethylene are known to cause sensory loss, anatomic resonance imaging (MRI) are normal, as is the cerebrospinal fluid (CSF). The function of the nerve may be studied by the electrical recording of blink reflexes. A few laboratories have developed an evoked potential test specifically of the trigeminal nerve. The difficult problem of chronic facial pain is discussed in Chap. 10.

Facial numbness also occurs with diverse conditions affecting the spinal nucleus of the trigeminal nerve, but in these cases there are additional signs of brainstem or upper cervical cord disease.

The Seventh, or Facial, Nerve

Anatomic Considerations The seventh cranial nerve is mainly a motor nerve supplying all the muscles concerned with facial expression on one side. The sensory component is small (the nervus intermedius of Wrisberg); it conveys taste sensation from the anterior two-thirds of the tongue and, variably, cutaneous sensation from the anterior wall of the external auditory canal. The taste fibers at first traverse the lingual nerve (a branch of the trigeminal mandibular) and then join the chorda tympani, which conveys taste sensation via the facial nerve to the nucleus of the tractus solitarius. Secretomotor fibers innervate the lacrimal gland through the greater superficial petrosal nerve and the sublingual and submaxillary glands through the chorda tympani (Fig. 47-3).

Several other anatomic facts are worth remembering. The motor nucleus of the seventh nerve lies ventral and lateral to the abducens nucleus, and the intrapontine fibers of the facial nerve partly encircle and pass ventrolaterally to the abducens nucleus before emerging from the pons, just lateral to the corticospinal tract. At their juxtaposition in the floor of the upper fourth ventricle, the sixth and seventh nerves may be affected simultaneously by a vascular or infiltrative lesion. The facial nerve enters the internal auditory meatus with the acoustic nerve and then bends sharply forward and downward around the anterior boundary of the vestibule of the inner ear. At this angle (gena) lies the sensory ganglion.

Spillane and Wells stressed an isolated trigeminal neuropathy (it has been called Spillane’s trigeminal neuritis in some texts). Four of their 16 patients had an associated parasanal sinusitis, but subsequent reports have failed to substantiate a causal relationship between sinusitis and cranial neuritis. One wonders how many of these individuals had connective tissue disease. A less common form of idiopathic trigeminal sensory neuropathy with which we have limited experience has a more acute onset and a tendency to resolve completely or partially, in much the same manner as Bell’s palsy, with which it is sometimes associated (Blau et al). A recurrent variety of uncertain origin has been reported in the dental literature. We have had experience with two patients whose facial numbness was a component of an upper cervical disc syndrome that included numbness on the same side of the body. Cases such as these are reported sporadically in the literature.

A pure unilateral trigeminal motor neuropathy is a clinical rarity. Chia has described five patients in whom an aching pain in the cheek and unilateral weakness of mastication were the main features. Electromyography (EMG) showed denervation changes in the ipsilateral masseter and temporalis muscles. The outcome was favorable.

In most cases of trigeminal neuropathy except those due to tumor and herpes zoster, the results of gadolinium-enhanced magnetic resonance imaging (MRI) are normal, as is the cerebrospinal fluid (CSF). The function of the nerve may be studied by the electrical recording of blink reflexes. A few laboratories have developed an evoked potential test specifically of the trigeminal nerve. The difficult problem of chronic facial pain is discussed in Chap. 10.

Facial numbness also occurs with diverse conditions affecting the spinal nucleus of the trigeminal nerve, but in these cases there are additional signs of brainstem or upper cervical cord disease.

### The Seventh, or Facial, Nerve

Anatomic Considerations The seventh cranial nerve is mainly a motor nerve supplying all the muscles concerned with facial expression on one side. The sensory component is small (the nervus intermedius of Wrisberg); it conveys taste sensation from the anterior two-thirds of the tongue and, variably, cutaneous sensation from the anterior wall of the external auditory canal. The taste fibers at first traverse the lingual nerve (a branch of the trigeminal mandibular) and then join the chorda tympani, which conveys taste sensation via the facial nerve to the nucleus of the tractus solitarius. Secretomotor fibers innervate the lacrimal gland through the greater superficial petrosal nerve and the sublingual and submaxillary glands through the chorda tympani (Fig. 47-3).

Several other anatomic facts are worth remembering. The motor nucleus of the seventh nerve lies ventral and lateral to the abducens nucleus, and the intrapontine fibers of the facial nerve partly encircle and pass ventrolaterally to the abducens nucleus before emerging from the pons, just lateral to the corticospinal tract. At their juxtaposition in the floor of the upper fourth ventricle, the sixth and seventh nerves may be affected simultaneously by a vascular or infiltrative lesion. The facial nerve enters the internal auditory meatus with the acoustic nerve and then bends sharply forward and downward around the anterior boundary of the vestibule of the inner ear. At this angle (gena) lies the sensory ganglion.
The most common disease of the facial nerve is Bell’s Palsy. The disorder affects men and women more or less equally and occurs at all ages and all times of the year. There is controversy regarding an increased incidence in women during the third trimester of pregnancy, particularly in the 2 weeks preceding delivery and in the first 2 weeks postpartum; up to a threefold increase has been cited by some authors, but others have failed to find this disproportionate number of cases. Supporting a proclivity for facial palsy are scattered reports of a recurrence with each pregnancy. Bell’s palsy is probably more common in diabetic patients and possibly in those with hypertension than in the healthy population.

As one might expect, the opportunity to examine the facial nerve in the course of Bell’s palsy occurs very rarely. Only a handful of such cases are on record, all showing varying degrees of degeneration of nerve fibers. One case was said to show inflammatory changes, but these may have been misinterpreted (see Karnes).

Regarding the causation of Bell’s palsy, a viral agent has long been suspected as discussed by Baringer. Only in the past few years, however, has such a mechanism been established with a reasonable degree of certainty for the majority of cases formerly considered to be idiopathic. Burgess and colleagues identified the genome of herpes simplex virus (HSV) in the geniculate ganglion of an elderly man who died 6 weeks after the onset of Bell’s palsy. Murakami and coworkers, using the polymerase chain reaction (PCR) technique to amplify viral genomic sequences, identified HSV type I in the endoneurial fluid surrounding the seventh nerve in 11 of 14 cases of Bell’s palsy; the fluid was obtained during surgical decompression of the nerve in ostensibly severe cases. The same investigators have produced facial paralysis by inoculating HSV into the ears and tongues of mice; virus antigens were then found in the facial nerve and geniculate ganglion. Varicella zoster virus (VZV) was not found in any of the Bell’s palsy patients but was isolated from patients with the Ramsay Hunt syndrome (page 642 and further on, page 1183). Control patients with fracture or infections of the temporal bone yielded neither HSV or VZV gene sequences. In the light of these findings, the term idiopathic facial paralysis, until now the accepted synonym for Bell’s palsy, is not entirely appropriate and perhaps herpes simplex or herpetic facial paralysis should be adopted.

The onset of Bell’s palsy is acute; about one-half of the cases attain maximum paralysis in 48 h and practically all within 5 days. Pain behind the ear may precede the paralysis by a day or two and in a few patients is quite intense and persistent. In only a small proportion of patients, a hypesthesia in one or more branches of the trigeminal nerve can be demonstrated. The explanation of this finding is not clear. Impairment of taste is present to some degree in most patients but rarely persists beyond the second week of paralysis. As indicated earlier, this indicates that the lesion has extended to or above the point where the chorda tympani fibers join the facial nerve. Hyperacusis or distortion of sound in the ipsilateral ear indicates paralysis of the stapedius muscle. Unlike the fifth nerve in cases of idiopathic trigeminal neuritis, the facial nerve in Bell’s palsy often displays enhancement on the gadolinium-enhanced MRI. Correspondingly, there is a mild increase of lymphocytes and mononuclear cells in the CSF in a few instances. Cases with more pronounced contrast enhancement of the facial nerve have a worse prognosis (Kress). Presumably, the enhancement reflects inflammation and swelling within the course of the facial nerve.

Fully 80 percent of patients recover within a month or two.
Recovery of taste precedes recovery of motor function; if the former occurs in the first week, it is a good prognostic sign. Early recovery of some motor function in the first 5 to 7 days is the most favorable prognostic sign. Electromyography may be of value in distinguishing temporary conduction defects from a pathologic interruption of nerve fibers; if there is evidence of denervation after 10 days, one may expect a long delay in the onset of recovery, measured in terms of months. Recovery then proceeds by regeneration of nerve, a process that may take 2 years or longer and is often incomplete.

Idiopathic Bell’s palsy is said to recur in 8 percent of cases (van Amstel and Devriese; Pitts et al), presumably as a result of reactivation of the latest herpesvirus. The palsy reemerges during an infection or pregnancy or for no apparent reason. The interval between episodes is unpredictable but has been 10 years, on average. Other recurrent forms of facial paralysis occur with Lyme disease and sarcoidosis, and in a familial variety as mentioned below.

**Treatment**  Protection of the eye during sleep, massage of the weakened muscles, and a splint to prevent drooping of the lower part of the face are the measures generally employed in the management of such cases. There is no evidence that surgical decompression of the facial nerve is effective, and it may be harmful. The administration of prednisone (40 to 60 mg/day, or an equivalent corticosteroid) during the first week to 10 days after onset has been beneficial in most trials. These medications are thought to decrease the possibility of permanent paralysis from swelling of the nerve in the tight facial canal.

The finding of viral genome surrounding the seventh nerve suggests that antiviral agents may be useful in the management of Bell’s palsy. However, several small trials have suggested that acyclovir, used alone, is no more effective than corticosteroids (De Diego et al). The use of both medications together remains under study. A retrospective report indicated that the outcome was better in 94 individuals with Bell’s palsy who were treated with acyclovir and prednisolone as compared to 386 treated only with prednisolone (Hato). Axelsson and associates similarly found that 56 patients treated with valacyclovir and prednisone had a somewhat better result than did the control patients. These data agree broadly with earlier studies suggesting benefit from the combined antiviral and steroid treatments (Adour et al). Given these reports, our impression is that treatment with steroids and acyclovir may be advisable, particularly early in the illness, but the small differences in outcome between groups in the aforementioned studies do not make this approach a necessity. In appropriate circumstances, testing should be undertaken for infectious causes that would require alternative therapy (e.g., Lyme, HIV, and perhaps mycoplasma). The treatment of facial palsy due to VZV (Ramsay Hunt syndrome) with antiviral drugs is discussed later.

**Other Causes of Facial Palsy**  Lyme disease commonly involves the facial nerve, as indicated on pages 768 and 1140. The mechanism is still uncertain but it is not thought to be attributable to a direct spirochetal infection. The diagnosis is likely when there has been a tick bite with well-documented erythema migrans or arthri-
Bilateral Facial Palsy  Bell’s palsy may be bilateral, but only rarely is the involvement on the two sides simultaneous. The truly contemporaneous appearance of bilateral facial paralysis (facial diplegia) is most often a manifestation of the Guillain-Barré syndrome (GBS) and may also occur in Lyme disease and rarely with HIV infection (page 644). There are numerous other causes of bilateral facial palsy, all of them infrequent (Keane). It is reported in approximately 7 of every 1000 patients with sarcoidosis although our impression is that it is more frequent. When acute in onset with sarcoidosis it has been referred to as uveoparotid fever, or Heerfordt syndrome. In typical cases of sarcoid the paralysis on each side tends to be separated by weeks or longer. Mononucleosis may affect both sides almost simultaneously; this is probably a form of GBS. Bilateral facial palsy is also a feature of the Möbius syndrome (page 873). Even less common is the Melkerson-Rosenthal syndrome, consisting of the triad of recurrent facial paralysis, facial (particularly labial) edema, and, less constantly, plication of the tongue. The syndrome begins in childhood or adolescence and may be familial. Biopsy of the lip may reveal a granulomatous inflammation. Causes of recurrent Bell’s palsy have been listed earlier and are summarized by Pitts and colleagues.

Supranuclear Forms of Facial Paralysis  All forms of nuclear or peripheral facial palsy must be distinguished from the supranuclear type. In the latter, the frontalis and orbicularis oculi muscles are involved less than those of the lower part of the face or not at all, since the corticopontine innervation of the upper facial muscles is bilateral, and that of the lower facial muscles mainly contralateral (a finding attributed to Broadbent, see page 46). In supranuclear lesions there may also be a dissociation of emotional and voluntary facial movements; often, some degree of paralysis of the arm and leg or an aphasia (in dominant hemisphere lesions) is conjoined. A developmental malformation of the perisylvian regions of the cortex may present as facial diplegia and pharyngeal paralysis, essentially a pseudobulbar palsy.

Muscles innervated by the facial nerve may be affected by lesions of the supranuclear pathways, which disinhibit or otherwise derange brainstem reflex activity. In the condition referred to as “apraxia of the eyelids,” the patients cannot close the eyelids voluntarily, but they will still close reflexively in response to stimulation of the supraorbital branch of the trigeminal nerve (by a tap on the brow or bridge of the nose or by touching the cornea). As described in Chap. 45, under “Blink Reflexes,” these are trigeminal reflexes. Actually, the blink reflex is expressed by two electrical responses, one early and mainly ipsilateral (termed R1) and the other late and bilateral (R2). The late response (to a tap on the brow), which is lost in Parkinson disease and is enhanced in pseudobulbar palsy, utilizes large fiber bundles in the supraorbital nerves; the early response (corneal reflex) utilizes the small fiber bundles in the long ciliary nerves. Derangement of one of these reflexes or of the jaw jerk is found in 25 percent of patients with multiple sclerosis. In pseudobulbar palsy, tapping the tendinous insertions into the orbicularis oris elicits a buccal (trigeminofacial) reflex, which may spread to cause closure of the eyes.

Facial Hemiatrophy (Parry-Romberg syndrome)  An obscure disorder is the facial hemiatrophy of Romberg. It occurs mainly in females and is characterized by a disappearance of fat in the dermal and subcutaneous tissues on one or both sides of the face. It usually begins in adolescence or early adulthood and is slowly progressive. In its advanced form, the affected side of the face is gaunt and the skin thin, wrinkled, and rather dark; the hair may turn white and fall out, and the sebaceous glands become atrophic; the muscles and bones are not involved as a rule. The condition is a form of lipodystrophy, but the localization within a myotome indicates the operation of some neural factor (possibly a growth factor) of unknown nature. A variegated coloration of the iris and a congenital oculosympathetic paralysis are found in some cases. Rarely certain
central nervous system abnormalities (mainly focal seizures and ventricular dilatation), referable to the homolateral hemisphere, are conjoined (Hosten). The significance of these associations is unclear. Wilson and Hoxie have pointed out the frequent coexistence of facial asymmetry in adults with congenital or early-onset superior oblique palsy and compensatory head tilt or torticollis.

If the peripheral facial paralysis has existed for some time and return of motor function has begun but is incomplete, a kind of contracture (in reality a continuous diffuse myokymic contraction) may appear. The palpebral fissure becomes narrowed, and the nasolabial fold deepens. Attempts to move one group of facial muscles result in contraction of all of them (associated movements, or synkinesis). Spasms of facial muscles may develop and persist indefinitely, being initiated by every facial movement. With the passage of time, the corner of the mouth and even the tip of the nose may become pulled to the affected side. This is a special acquired form of hemifacial spasm, the more common variety of which is described below.

Anomalous regeneration of the seventh nerve fibers, following Bell’s palsy or other injury, may result in other curious disorders that represent limited types of synkineses. The most common is the “jaw-winking” phenomenon (also called Wartenberg’s or inverse Marcus-Gunn sign), in which jaw movements, especially lateral movements (engaging the pterygoid muscle), cause an involuntary closure of the eyelid ipsilateral to the movement. If regenerating fibers originally connected with the orbicularis oculi become connected with the orbicularis oris, closure of the lids may cause a retraction of the corner of the mouth; or if visceromotor fibers originally innervating the salivary glands later come to innervate the lacrimal gland, anomalous tearing (crocodile tears) occurs whenever the patient salivates. A similar mechanism explains gustatory sweating of the cheek and upper lip.

Hemifacial Spasm The facial muscles on one side may be involved in painless irregular clonic contractions of varying degree (hemifacial spasm). This condition develops in the fifth and sixth decades, affects women more than men, and it usually proves to be due to a compressive lesion of the facial nerve, most often by a tortuous branch of the basilar artery that lies on the ventral surface of the pons and forms a loop under the proximal nerve. Less often the cause of compression is a basilar artery aneurysm, or an acoustic nerve tumor or meningioma. The spasm usually begins in the orbicularis oculi muscle and gradually spreads to other muscles on that side of the face, including the platysma. The paroxysm may be induced or aggravated by voluntary and reflexive movements of the face.

There was for a time controversy concerning the pathogenesis of hemifacial spasm. Jannetta attributed all cases to a compression of the root of the facial nerve by an aberrant looped blood vessel. Microsurgical decompression of the root with the interposition of a pledge between the vessel and the root has relieved the facial spasm in most of his cases. These results have been corroborated by Barker and associates in a series of 705 patients followed postoperatively for an average period of 8 years; 84 percent achieved an excellent result. An even higher rate of benefit was obtained in a prospective series by Illingworth and colleagues (cure of 81 of 83 patients).

The pathophysiology of the spasm is believed to be focal demyelination nerve root compression. The demyelinated axon is theorized to activating adjacent nerve fibers by ephaptic transmission (“artificial” synapse of Granit et al). Another possible source of the spasm is spontaneous ectopic excitation arising in injured fibers. Nielsen and Jannetta have shown that ephaptic transmission disappears after the nerve is decompressed.

Treatment Surgical decompression of a vascular loop, which involves exploration of the posterior fossa, carries some small risk. The facial muscles may be weakened, sometimes permanently. Another complication has been deafness due to injury of the adjacent eighth nerve. Also, there is a modest risk of recurrence of the spasms, usually within 2 years of the operation (Piatt and Wilkins). Operative success depends on tight dural closure to prevent CSF leakage from the posterior fossa.

The authors suggest that patients with idiopathic hemifacial spasm should first be treated medically. Alexander and Moses noted that carbamazepine (Tegretol) in a dosage of 600 to 1200 mg/day controlled the spasm in two thirds of the patients. Baclofen or gabapentin can be tried if carbamazepine fails. Some patients cannot tolerate these drugs, have only brief remissions, or fail to respond; they may be treated with botulinum toxin injected into the orbicularis oculi and other facial muscles. The hemifacial spasms are relieved for 4 to 5 months and injections can be repeated without danger. Some patients have been injected repeatedly for more than 5 years without apparent adverse effects. Failing these conservative measures, surgery is quite appropriate.

Other Disorders of the Facial Nerve Facial myokymia is a fine rippling activity of all the muscles of one side of the face mentioned above. It develops most often in the course of multiple sclerosis or a brainstem glioma. It has also occurred after other diseases of the facial nerve, e.g., in GBS, in which case it is usually bilateral. We have seen it more often in the recovery stage than in the early phase of GBS. The fibrillar nature of the involuntary movements and their arrhythmicity tend to distinguish them from the coarser intermittent facial spasms and contracture, tics, tardive dyskinesia, and clonus. The EMG pattern is one of spontaneous asynchronous discharge of adjacent motor units, appearing singly or in doublets or triplets at a rate varying from 30 to 70 cycles per second. Demyelination of the intrapontine part of the facial nerve and possibly supranuclear disinhibition of the facial nucleus have been the postulated mechanisms. But the observation of facial myokymia in GBS informs us that the abnormal movement may have its origin in a lesion at any point along the nerve (see pages 1194 and 1278 for further discussion of myokymia).

A clonic or tonic contraction of one side of the face may be the sole manifestation of a cerebral cortical seizure. Involuntary recurrent spasm of both eyelids (blepharospasm) may occur with almost any form of dystonia but is most frequent in elderly persons as an isolated phenomenon, and there may be varying degrees of spasm of the other facial muscles (see page 93). Relaxant and tranquilizing drugs are of little help in this disorder, but injections of botulinum toxin into the orbicularis oculi muscles give temporary or lasting relief. A few of our patients have been helped (paradoxically) by L-dopa; baclofen, clonazepam, and tetrabenazine in increasing doses may be helpful. In the past, failing these measures, the periorbital muscles were destroyed by injections of doxorubicin or surgical myectomy (Hallett and Daroff). With the advent of botulinum treatment, there is no longer a need to resort to these extreme measures. In some cases, blepharospasm subsides spontaneously. Rhythmic unilateral myoclonia, akin to palatal myoclonus, may be restricted to facial, lingual, or laryngeal muscles.

Hypersensitivity of the facial nerve occurs in hypocalcemic
tetany; spasm of the facial muscles is elicited by tapping in front of the ear (Chvostek sign).

The Ninth, or Glossopharyngeal, Nerve

Anatomic Considerations This nerve arises from the lateral surface of the medulla by a series of small roots that lie just rostral to those of the vagus nerve. The glossopharyngeal, vagus, and spinal accessory nerves leave the skull together through the jugular foramen and are then distributed peripherally. The ninth nerve is mainly sensory, with cell bodies in the inferior, or petrosal, ganglion (the central processes of which end in the nucleus solitarius) and the small superior ganglion (the central fibers of which enter the spinal trigeminal tract and nucleus). Within the nerve are different fibers from baroreceptors in the wall of the carotid sinus and from chemoreceptors in the carotid body. The baroreceptors are involved in the regulation of blood pressure, and chemoreceptors are responsible for the ventilatory responses to hypoxia. The somatic efferent fibers of the ninth nerve are derived from the nucleus ambiguus, and the visceral efferent (secretory) fibers, from the inferior salivatory nucleus. These fibers contribute in a limited way to the motor innervation of the striated musculature of the pharynx (mainly of the stylopharyngeus, which elevates the pharynx), the parotid gland, and the glands in the pharyngeal mucosa. A discussion of its role in swallowing is found on page 476.

It is commonly stated that this nerve mediates sensory impulses from the faucial tonsils, posterior wall of the pharynx, and part of the soft palate as well as taste sensation from the posterior third of the tongue. However, an isolated lesion of the ninth cranial nerve is a rarity, and the effects are not fully known. In one personally observed case of bilateral surgical interruption of the ninth nerves, verified at autopsy, there had been no demonstrable loss of taste or other sensory or motor impairment. This suggests that the tenth nerve may be responsible for these functions, at least in some individuals. The role of the ninth nerve in the reflex control of blood pressure and ventilation has been alluded to earlier but referable clinical manifestations from damage of this cranial nerve are infrequent except perhaps for syncope as noted below.

One may occasionally observe a glossopharyngeal palsy in conjunction with vagus and accessory nerve involvement due to a tumor in the posterior fossa or an aneurysm of the vertebral artery. The nerves are compressed as they pass through the jugular foramen. Hoarseness due to vocal cord paralysis, some difficulty in swallowing, deviation of the soft palate to the sound side, anesthetic of the posterior wall of the pharynx, and weakness of the upper trapezius and sternomastoid muscles make up the clinical picture (see Table 47-1, jugular foramen syndrome). On leaving the skull, the ninth, tenth, and eleventh nerves lie adjacent to the internal carotid artery, where they can be damaged by a dissection of that vessel.

Glossopharyngeal Neuralgia (see also page 163) This disorder first described by Weisenburg in 1910 resembles trigeminal neuralgia in many respects except that the unilateral stabbing pain is localized to one side of the root of the tongue and throat. It is far less common than trigeminal neuralgia. Sometimes the pain overlaps the vagal territory beneath the angle of the jaw and external auditory meatus. It may be triggered by coughing, sneezing, swallowing, and pressure on the tragus of the ear. Temporary blocking of the pain by anesthetizing the tonsillar faucae and posterior pharynx with 10% lidocaine spray is diagnostic. Rarely, herpes zoster may involve the glossopharyngeal nerve. Fainting as a manifestation of vagoglossopharyngeal neuralgia is described on page 325.

The same drugs that have been found helpful in the treatment of tic douloureux may be used to treat glossopharyngeal neuralgia, but their efficacy has been difficult to judge. Regarding vascular compression of the nerve, Resnick and colleagues have reported the results of microvascular decompression of the ninth nerve in 40 patients; in 32 of these, relief of symptoms was complete and was sustained during an average follow-up of 4 years; 3 patients remained with permanent weakness of structures thought to be innervated by the ninth nerve. A similar high rate of success has been achieved by others. If syncope is associated with the pain, it can be expected to cease with abolition of the attacks of pain. Syncope can also occur when the ninth nerve is involved by tumors of the parapharyngeal space; most of these are squamous cell carcinomas and both the ninth and tenth nerves are implicated. Section of rootlets of the ninth nerve has reportedly reduced or abolished the episodes of fainting in these cases.

The Tenth, or Vagus, Nerve

Anatomic Considerations This nerve has an extensive sensory and motor distribution and important autonomic functions. It has two ganglia: the jugular, which contains the cell bodies of the somatic sensory nerves (innervating the skin in the concha of the ear), and the nodose, which contains the cell bodies of the afferent fibers from the pharynx, larynx, trachea, esophagus, and thoracic and abdominal viscera. The central processes of these two ganglia terminate in relation to the nucleus of the spinal trigeminal tract and the tractus solitarius, respectively. The motor fibers of the vagus are derived from two nuclei in the medulla—the nucleus ambiguus and the dorsal motor nucleus. The former supplies somatic motor fibers to the striated muscles of the larynx, pharynx, and palate; the latter supplies visceral motor fibers to the heart and other thoracic and abdominal organs. The distribution of vagal fibers is illustrated in Fig. 47-4, and their participation in swallowing is described on page 476.

Complete interruption of the intracranial portion of one vagus nerve results in a characteristic paralysis. The soft palate droops on the ipsilateral side and does not rise in phonation. The uvula deviates to the normal side on phonation, but this is an inconstant sign in disease. There is loss of the gag reflex on the affected side and of the curtain movement of the lateral wall of the pharynx, whereby the faucial pillars move medially as the palate rises in saying “ah.” The voice is hoarse, often nasal, and the vocal cord on the affected side lies immobile in a “cadaveric” position, i.e., midway between abduction and adduction. With partial lesions, movements of abduction are affected more than those of adduction (Semon’s law). There may be a loss of sensation at the external auditory meatus and back of the pinna. Usually no change in visceral function can be demonstrated. If the pharyngeal branches of both vagi are affected, as in diphtheria, the voice has a nasal quality, and regurgitation of liquids through the nose occurs during the act of swallowing.

Diseases Affecting the Vagus Complete bilateral paralysis is said to be incompatible with life, and this is probably true if the nuclei are entirely destroyed in the medulla by poliomyelitis or some other disease. However, in the cervical region, both vagi have been blocked with procaine in the treatment of intractable asthma without mishap. Moreover, Johnson and Stern report a case of bi-
lateral vocal cord paralysis in association with familial hypertrophic polyneuropathy, and Plott relates the history of three brothers with congenital laryngeal abductor paralysis due to bilateral dysgenesis of the nucleus ambiguus. Bannister and Oppenheimer have called attention to defects of phonation and laryngeal stridor as early features of autonomic failure in multiple system atrophy (page 925). We have seen several such patients in whom stridor was a prominent feature of the illness, in one patient for 7 months before other features of the disease became evident.

The vagus nerve may be implicated at the meningeal level by tumors and infectious processes and within the medulla by vascular lesions (e.g., the lateral medullary syndrome of Wallenberg or a cavernous angioma), by motor system disease, and occasionally by tumors. Dysphagia is then invariably present. Herpes zoster may attack this nerve, either alone or together with the ninth nerve as part of a jugular foramen syndrome. The vagus is often affected along with the glossopharyngeal nerve in spontaneous dissection of the carotid artery at the base of the skull. The vagus nerves may be damaged in the course of thyroid surgery and may be involved in cases of advanced alcoholic or diabetic neuropathy. Polymyositis and dermatomyositis, which cause hoarseness and dysphagia by direct involvement of laryngeal and pharyngeal muscles, thereby simulate disease of the vagus nerves.

A fact of some importance is that the left recurrent laryngeal nerve, because of its long course under the aortic arch, may be damaged as a result of thoracic disease. There is no dysphagia with lesions at this point in the nerve since the branches to the pharynx (but not to the larynx) have already been given off. For this reason, an aneurysm of the aortic arch, an enlarged left atrium, mediastinal lymph nodes from bronchial carcinoma, and a mediastinal or superior sulcus lung tumor are much more frequent causes of an isolated (left) vocal cord palsy than are intracranial diseases.

It is estimated that in one-quarter to one-third of all cases of paralysis of the recurrent laryngeal nerve no cause can be established, i.e., they are idiopathic. The highest incidence is in the third decade, and males are more susceptible than females. Of the 21 cases reported by Blau and Kapadia, 5 recovered completely and 5 partially within a few months; no other disease appeared in the 8-year period that followed. Palsies of the superior and recurrent laryngeal nerves, occurring as part of isolated vagal neuropathies, have been described by Berry and Blair. A few were bilateral, and again, the majority of the cases were idiopathic and had much the same prognosis as isolated palsies of the recurrent laryngeal nerve.

Laryngeal neuralgia is a rare entity, in which paroxysms of pain are localized over the upper portion of the thyroid cartilage or hyoid bone on one or both sides. It is evoked by coughing, yawning, talking, or sneezing. In the case reported by Brownstone and coworkers it was relieved by carbamazepine.

**Diagnosis** When confronted with a case of vocal cord palsy, the physician is advised to determine the site of the lesion. If intramedullary, there are usually ipsilateral cerebellar signs, loss of pain and temperature sensation over the ipsilateral face and contralateral arm and leg, and an ipsilateral Bernard-Horner syndrome (Table 34-3). If the lesion is extramedullary but intracranial, the glossopharyngeal and spinal accessory nerves are frequently involved as well (jugular foramen syndrome, see Table 47-1). If extracranial in the posterior laterocondylar or retroperatoid space, there may be a combination of ninth, tenth, eleventh, and twelfth cranial nerve palsies and a Bernard-Horner syndrome. Combinations of these lower cranial nerve palsies, which have a variety of eponymic designations (see Table 47-1), are caused by various tumors, both primary and metastatic, or by chronic inflammations or granulomas involving lymph nodes at the base of the skull. If there is no palatal weakness and no pharyngeal or palatal sensory loss, the lesion is below the origin of the pharyngeal branches, which leave the vagus nerve high in the cervical region. The usual site of disease is then the mediastinum.
The Eleventh, or Spinal Accessory, Nerve

Anatomic Considerations  This is a purely motor nerve, of spinal rather than cranial origin. Its fibers arise from the anterior horn cells of the upper four or five cervical segments and enter the skull through the foramen magnum. Intracranially, the accessory nerve travels for a short distance with the part of the tenth nerve that is derived from the caudalmost cells of the nucleus ambiguus; together, the two roots are referred to as the vagal-accessory nerve or cranial root of the accessory nerve. The two roots leave the skull through the jugular foramen. The aberrant vagus fibers then rejoin the main trunk of the vagus, and the fibers derived from the cervical segments of the spinal cord form an “external ramus” and innervate the ipsilateral sternocleidomastoid and trapezius muscles. Only the somatic motor fibers constitute the accessory nerve in the strict sense. In patients with torticollis, however, division of the upper cervical motor roots or the spinal accessory nerve has often failed to ablate completely the contraction of the sternocleidomastoid muscle. This suggests a wider innervation of the muscle, perhaps by fibers of apparent vagal origin that join the accessory nerve for passage through the jugular foramen.

A complete lesion of the accessory nerve results in weakness of the sternocleidomastoid muscle and upper part of the trapezius (the lower part of the trapezius is innervated by the third and fourth cervical roots through the cervical plexus). Weakness can be demonstrated by asking the patient to shrug his shoulders; the affected side will be found to be weaker, and there will often be evident atrophy of the upper part of the trapezius. With the arms at the sides, the shoulder on the affected side droops and the scapula is slightly winged; the latter defect is accentuated with lateral movement of the arm (with serratus anterior weakness, winging of the scapula is more prominent and occurs on forward elevation of the arm). When the patient turns his head forcibly against the examiner’s hand, preferably starting with the head deviated to the opposite side, the sternocleidomastoid of the opposite side does not contract firmly beneath the fingers. This muscle can be further tested by having the patient press his head forward against resistance or lift his head from the pillow.

Motor system disease, poliomyelitis, syringomyelia, and spinal cord tumors may involve the cells of origin of the spinal accessory nerve. In its intracranial portion, the nerve is usually affected along with the ninth and tenth cranial nerves by herpes zoster or by lesions of the jugular foramen (glomus tumors, neurofibromas, metastatic carcinoma, jugular vein thrombosis). Tumors at the foramen magnum may also damage the nerve. In the posterior triangle of the neck, the eleventh nerve can be damaged during surgical operations and by external compression or injury. Compressive-invasive lesions of this nerve may be visualized by computed tomography or MRI of the posterior cervical space.

A benign disorder of the eleventh nerve, akin to Bell’s palsy, has been described by Spillane and by Eisen and Bertrand. It begins with pain in the low lateral neck that subsides in a few days and is followed by weakness and atrophy in the distribution of the nerve. Also, a recurrent form of spontaneous accessory neuritis has been described (Chalk and Isaacs). About one quarter to one third of eleventh nerve lesions are estimated to be of this idiopathic type; most but not all of the patients recover.

Bilateral sternocleidomastoid and trapezius palsy, which occurs with primary disease of muscles—e.g., polymyositis and muscular dystrophy—may be difficult to distinguish from a bilateral affection of the accessory nerves or the motor nuclei (progressive bulbar palsy). The supranuclear innervation of the spinal accessory nuclei is apparently mainly ipsilateral as evidenced by contraversive turning of the head during a seizure, the result of contraction of the ipsilateral sternocleidomastoid muscle. Whether this is attributable to a direct ipsilateral tract, or to double crossing, is not known.

The Twelfth, or Hypoglossal, Nerve

Anatomic Considerations  This is also a pure motor nerve, which supplies the somatic musculature of the tongue. It arises as a series of rootlets that issue from the ventral medulla between the pyramid and inferior olivary complex. The nerve leaves the skull through the hypoglossal foramen and innervates the genioglossus muscle, which acts to protrude the tongue; the styloglossus, which retracts and elevates its root; and the hypoglossus, which causes the upper surface to become convex. Complete interruption of the nerve results in paralysis of one side of the tongue. The tongue curves slightly to the healthy side as it lies in the mouth, but on protrusion it deviates to the affected side, owing to the unopposed contraction of the healthy genioglossus muscle. By pressing against the tongue in the cheek, one can judge the degree of weakness. The tongue also cannot be moved with natural facility causing difficulty with handling food in the mouth. The denervated side becomes wrinkled and atrophied, and fasciculations and fibrillations can be seen.

Lesions of the hypoglossal nerve roots are rare. Occasionally an intramedullary lesion, usually a stroke, damages the emerging fibers of the hypoglossal nerve, corticospinal tract, and medial lemniscus (Table 34-3). The result is paralysis and atrophy of one side of the tongue, together with spastic paralysis and loss of vibration and position sense in the opposite arm and leg. Poliomyelitis and motor system disease may destroy the hypoglossal nuclei. Lesions of the basal meninges and of the occipital bones (tumor invasion platybasia, invagination of the occipital condyles, Paget disease) may involve the nerve in its extramedullary course, and it is sometimes damaged in operations on the neck. A dissecting aneurysm of the carotid artery was shown by Goodman and coworkers to have compressed the hypoglossal nerve, with resultant weakness and atrophy of the tongue. Rare instances of temporal arteritis and Takayasu arteritis affecting the carotid artery and adjacent twelfth nerve have been described. Lance and Anthony have described the simultaneous occurrence of nuchal-occipital pain and ipsilateral numbness of the tongue, provoked by the sudden, sharp turning of the head and termed it the neck-tongue syndrome. The phenomenon is attributed to compression, in the atlantoaxial space, of the second cervical root, which carries some of the sensory fibers from the tongue, via the hypoglossal nerve, to the C2 segment of the spinal cord.

It is worth mentioning here that the tongue may be red and smooth in vitamin deficiency states. Glossodynia (burning pain of the tongue, burning mouth syndrome, page 165), a condition most frequently seen in the elderly and unexplained in young women, may or may not be accompanied by redness and dryness, but not by weakness. A habit of tongue-thrusting and teeth-clenching is often associated. The ascription of these motor abnormalities to a psychogenic mechanism does not agree with the authors’ experience (see Quinn).

Syndrome of Bulbar Palsy

This syndrome is the result of weakness or paralysis of muscles that are supplied by the motor nuclei of the lower brainstem, i.e.,
the motor nuclei of the fifth, seventh, and ninth to twelfth cranial nerves. (Strictly speaking, the motor nuclei of the fifth and seventh nerves lie outside the “bulb,” which is the old name for the medulla oblongata.) Involved are the muscles of the jaw and face; the sternocleidomastoid and upper parts of the trapezius; and the muscles of the tongue, pharynx, and larynx. If weakness develops rapidly, as may happen in GBS, diphtheria, or polymyelitis, there is no time for muscle atrophy. Myasthenia gravis, inclusion body myopathy, and polymyositis may on rare occasions produce such a picture but motor neuron disease is the most common course. When the latter disease is isolated to the bulbar muscles, it has been called progressive bulbar palsy. The more chronic diseases—e.g., progressive bulbar palsy and Kennedy bulbospatial atrophy (forms of motor system disease) and the childhood form of Fazio-Londe—result in marked wasting and fasciculation of the facial, tongue, sternocleidomastoid, and trapezius muscles. All of these disorders must be differentiated from pseudobulbar palsy (see page 426).

### MULTIPLE CRANIAL NERVE PALSYs

As one can readily understand, several cranial nerves may be affected by a single disease process. The first clinical problem that arises is whether lesions lie within or outside the brainstem. Lesions lying on the surface of the brainstem or at the base of the skull are characterized by involvement of adjacent cranial nerves (often occurring in succession and sometimes painful) and by late and only slight, if any, involvement of the long sensory and motor pathways. These are discussed below and listed in Table 47-1 by their eponymic designations. The opposite is true of intramedullary, intrapontine, and intrasmesencephalic lesions; lesions within the brainstem that involve cranial nerves often produce a crossed-sensory or motor paralysis (cranial nerve signs on one side of the body and tract signs on the opposite side). In this way, a number of distinctive brainstem syndromes, to which eponyms have been attached, are produced. These are listed in Table 34-3. An extramedullary lesion is more likely to cause bone erosion or to be associated with encroachment on cranial nerves (seen radiographically). The special problems of multiple cranial nerve palsies of the ocular motor nerves are addressed in Chap. 14.

*Involvement of multiple cranial nerves outside the brainstem* may be the result of trauma (obviously sudden in onset); localized infections such as herpes zoster (less acute onset); Lyme disease as reported by Schmutzhard and colleagues; cytomegalovirus (CMV) infection in an AIDS patient; Wegener granulomatosis, sarcoidosis, or other types of granulomatous disease (subacute onset); or compression by tumors and saccular aneurysms (more chronic development with pain). The sequential painless affection of contiguous or noncontiguous nerves over several days or weeks is particularly characteristic of meningeval carcinomatosis or lymphomatosis. The eighth nerve is commonly incorporated in neoplastic meningeval infiltrations. Among the solid tumors that cause local compression of nerves, neurofibromas, schwannomas (acoustic neuroma), meningiomas, cholesteatomas, cordomas, and chondromas have all been observed. Nasopharyngeal carcinoma (Schmincke tumor or lymphoepithelioma) may implicate several cranial nerves in succession by invading the base of the skull (mainly the fifth and sixth but also higher nerves; Fig. 47-5), as do basilar invagination and Chiari malformation. Several lower cranial nerves may be involved on one side by a carotid artery dissection. In France, a successive involvement of all cranial nerves on one side has been called the Garcia syndrome, or hemibasal

![Figure 47-5. Nasopharyngeal carcinoma invading the anterior base of the skull and causing third and fifth nerve palsies. Coronal CT scan with bone windows.](image)

Viral infections of cranial nerves is always raised by acute neuropathies of the facial, trigeminal, and auditory nerves, especially when the condition is bilateral, involves several nerves in combination, or is associated with a pleocytosis in the spinal fluid. Actually, the only proved viral etiology in this group of cases is that of herpes simplex and herpes zoster infections causing Bell’s palsy, as discussed earlier. Since perceptive deafness, vertigo, and other cranial nerve palsies have been observed in conjunction with the postinfectious encephalomyelitides of Mycoplasma, varicella, measles, rubella, mumps, and scarlet fever they probably share an immune-mediated mechanism. However, as discussed in Chaps. 33 and 36, new techniques that identify small components of the genome of these organisms indicate that some cases formerly thought to be postinfectious in nature may be true infections of the nerve. The same may be said of the single and multiple cranial nerve palsies that are sometimes associated with HIV and CMV infections. Nothing is known of the pathology of the cranial nerve lesion or has a virus been isolated in these latter infections. Treatment of the parainfectious cases is symptomatic; fortunately the prognosis for recovery is excellent. The main causes of bilateral facial palsy have been discussed earlier in the chapter. A purely motor disorder of the facial and oropharyngeal muscles without atrophy always raises the question of myasthenia gravis.

From time to time one observes an acute form of multiple cranial neuropathy of undetermined cause. Juncos and Beal reported on 14 cases of this type, along with 6 well-documented cases of the Tolosa-Hunt orbitocavernous sinus syndrome with ocular motor palsies (see page 234). In the former group, the onset was usually pain and headache (temporofrontal), followed within days by abducens palsy (12 of 14), oculomotor palsy (6 of 14), trigeminal palsy (5 of 14), facial weakness (4 of 14), and less often by involvement of the eighth, ninth, and tenth cranial nerves (unilaterally in most instances). Increased protein of CSF and pleocytosis occurred in several. The prompt relief of pain upon administration of steroids was similar to that obtained in the Tolosa-Hunt syndrome. The mode of recovery, which usually occurred within a few months, was also much the same in the two groups of patients. Juncos and Beal concluded that the clinical features of the two groups overlapped and that their separation into two syndromes was arbitrary. We have seen a relapsing form of this illness in young adults, responsive on each occasion to steroids. Numerous tests of the CSF by polymerase chain reaction revealed no viruses. Conceivably, some of these cases represent a variant form of GBS, inasmuch as they may be preceded by a nonspecific infection and accompanied by areflexia, evanescent paresthesias or weakness of the extremities, and an elevated CSF protein without pleocytosis. Others probably are examples of the entity described by Juncos and Beal, possibly reflecting a granulomatous process in the pachymeninges. As a more chronic affliction, we have observed 10 cases in which cranial nerves were affected sequentially over a period of many years (polyneuritis cranialis multiplex). Two were later found to have tuberculosis of cervical lymph nodes (presumably scrofula), and three had sarcoidosis. No cause was determined in the rest. Symonds had similar experience. It is usually worth obtaining a biopsy of an enlarged cervical lymph node in these circumstances. Corticosteroid treatment seemed to have been helpful in our cases.

The special case of painless multiple oculomotor palsies is discussed in Chap. 14. The main causes are GBS, botulism, myasthenia gravis, thyroid ophthalmopathy, and diphtheria. In cases of chronic evolution, oculopharyngeal dystrophy and mitochondrial myopathy (progressive external ophthalmoplegia) must also be considered.

In cases of Tolosa-Hunt syndrome in which the orbital or cavernous sinus has been biopsied, a nonspecific granuloma has been found. Sarcoid and tuberculosis have been the causes of a few cases, as noted earlier. In Wegener granulomatosis, multiple cranial nerve palsies, usually lower ones, are reported. The administration of cyclophosphamide has led to remission (page 732). The cavernous sinus syndrome, discussed on pages 229 and 735, consists of various combinations of oculomotor palsies and upper trigeminal sensory loss, usually accompanied by signs of increased pressure or inflammation of the venous sinus. The third, fourth, fifth, and sixth cranial nerves are affected first on one side only, but any of the processes that infiltrate or obstruct the sinus may spread to the other side. The main causes are septic or aseptic thrombosis of the venous sinus due to trauma, hypercoagulable states, or adjacent infections in adjacent structures, carotid artery aneurysm, and neoplastic infiltration. Keane summarized his experience with an astonishing 151 instances of cavernous sinus syndrome and found trauma and surgical procedures to be the most common causes, followed by neoplasms (specifically those originating in the nasopharynx), pituitary tumors, metastases, and lymphomas; our experience has tended more toward local infectious causes in diabetic patients and hypercoagulable states.

A special case of multiple cranial nerve palsies that has been brought to our attention is an infiltration along the distal nerves in the skin and subcutaneous tissues by squamous cell carcinomas of the face, especially the spindle cell and other atypical varieties of tumor. This type of perineural spread first causes very restricted unilateral palsies related to the superficial branches of the fifth and seventh cranial nerves in one region of the face and then extends to the base of the skull and to the ventral brainstem. According to Clouston and colleagues, who present 5 cases in detail, the initial symptoms are usually pain and numbness in the area underlying the skin lesion and facial weakness confined to the same regions of the face; this pattern is a result of the proximity of fifth and seventh nerve branches in the skin and subcutaneous tissues. Various combinations of oculomotor palsies may follow as a result of tumor entry into the orbit via the infraorbital branch of the maxillary nerve. Occasionally there is no pain. We have also observed a similar regional pattern of extracranial involvement of trigeminal and facial nerves with an infiltrative mixed-cell tumor of the parotid gland.

CHAPTER 48
PRINCIPLES OF CLINICAL MYOLOGY: DIAGNOSIS AND CLASSIFICATION OF DISEASES OF MUSCLE AND NEUROMUSCULAR JUNCTION

GENERAL CONSIDERATIONS

Skeletal, or voluntary, muscle constitutes the principal organ of locomotion as well as a vast metabolic reservoir. Disposed in more than 600 separate muscles, this tissue makes up as much as 40 percent of the weight of adult human beings. An intricacy of structure and function undoubtedly accounts for its diverse susceptibility to disease, for which reason the main anatomic and physiologic facts are provided as an introduction to the following several chapters on muscle disease. For the purposes of exposition, diseases of the neuromuscular junction are presented in the chapters that follow (Chap. 53).

A single muscle is composed of thousands of muscle fibers that extend for variable distances along its longitudinal axis. Each fiber is a relatively large and complex multinucleated cell varying in length from a few millimeters to several centimeters (34 cm in the human sartorius muscle) and in diameter from 10 to 100 μm. Some fibers span the entire length of the muscle; others are joined end to end by connective tissue. Each muscle fiber is enveloped by an inner plasma membrane (the sarcolemma) and an outer basement membrane. The multiple nuclei of each fiber (cell), which are oriented parallel to its longitudinal axis and may number in the thousands, lie beneath the plasma membrane (sarcolemma)—hence they are termed subsarcolemmal or just sarcolemmal nuclei.

The cytoplasm (sarcoplasm) of the cell is abundant and contains myofibrils, various organelles such as mitochondria and ribosomes; each myofibril is enveloped in a membranous net, the sarcoplasmic reticulum (SR; Fig. 45-2). Extensions of the plasma membrane into the fiber form the transverse tubular system (T tubules), which are extracellular channels of communication with the intracellular sarcoplasmic reticulum. The SR and T tubules are anatomically independent but functionally related membrane systems. The junctional gap between the T tubules and SR is occupied by protein formations that are attached to the SR and are referred to as junctional feet; the latter have been identified as ryanodine receptors and are responsible for the release of calcium from the SR, which is a critical step in exciting the muscle (see Franzini-Armstrong).

The myofibrils themselves are composed of longitudinally oriented interdigitating filaments (myofilaments) of contractile proteins (actin and myosin), additional structural proteins (titin and nebulin), and regulatory proteins (tropomyosin and troponin). The series of biochemical events by which these proteins, under the influence of calcium ions, accomplish the contraction and relaxation of muscle is described in Chap. 45. Droplets of stored fat, glycogen, various proteins, many enzymes, and myoglobin, the latter imparting the red color to muscle, are contained within the sarcoplasm or its organelles.

Although the muscle fiber represents an indivisible anatomic and physiologic unit, disease may affect only one part of it, leaving the remainder to become dysfunctional or to atrophy, degenerate, or regenerate, depending on the nature and severity of the disease process.

The individual muscle fibers are surrounded by delicate strands of connective tissue (endomysium), which provide their support and permit unity of action. Capillaries, of which there may be several for each fiber, and nerve fibers, lie within the endomysium. Muscle fibers are bound into groups or fascicles by similar reticular tissue and sheets of collagen (perimysium), which bind together groups of fascicles and also surround the entire muscle (epimysium). The latter connective tissue tunics are also richly vascularized; different types of muscle have different arrangements of arteries and veins; fat cells are embedded within the interstices. The muscle fibers are attached at their ends to tendon fibers, which in turn connect with the skeleton. By this means, muscle contraction maintains posture and imparts movement.

Other notable characteristics of muscle are its natural mode of contraction—i.e., through neural innervation—and the necessity of intact innervation for the maintenance of its normal tone and tropic state. Each muscle fiber receives a nerve twig from a motor nerve cell in the anterior horn of the spinal cord or nucleus of a cranial nerve; the nerve twig joins the muscle fiber at the neuromuscular junction or motor end plate. As was pointed out on page 39, groups of muscle fibers with a common innervation from one anterior horn cell constitute the motor unit, which is the basic physiologic unit in all reflex, postural, and voluntary activity.

Embedded in the surface membrane are several types of ion channels that are responsible for maintaining the electrical potential and propagating depolarizing currents across the muscle membrane. Diseases of these channels are discussed in Chap. 54. Also constituting a large part of the membrane is a series of anchoring structural proteins, the nature of which have been thoroughly elucidated only in the past few decades. These are described in detail in relation to the muscular dystrophies in Chap. 50.

Acetylcholine (ACh), ACh receptors, and acetylcholinesterase (AChE), all of which play a special role in neuromuscular transmission, are concentrated at the neuromuscular junction. ACh is synthesized in the motor nerve terminal and stored in vesicles as packets, or “quanta,” each containing a relatively fixed number of molecules (about 10,000). Quanta of ACh are released at the nerve ending, diffuse into the narrow synaptic cleft, and combine with specialized receptors on the postsynaptic membrane. On the postsynaptic side of the synapse, the released ACh binds to ligand-
gated cation channels, which are concentrated at the peaks of the neuromuscular clefts. This creates a current that propagates toward the bottom of the cleft and opens voltage-gated sodium channels and results in a depolarizing potential of the muscle membrane. Small numbers of quanta of ACh are released spontaneously, producing miniature end-plate potentials (MEPPs) of about 0.5 mV. A nerve impulse arriving at the presynaptic distal axon causes an ingress of calcium into the nerve terminal through voltage-gated calcium channels, thereby triggering the release of many ACh quanta and producing a much larger end-plate potential (EPP). This wave of depolarization is propagated along the sarcolemma and transverse tubules to the interior of the fibers and leads to muscle contraction (see Chap. 45). The process of ACh release is terminated by action of the enzyme AChE, which breaks down ACh at the neuromuscular junction. AChE is concentrated at the bottom of the synaptic cleft. For the details of exocytosis of the synaptic vesicles and their reconstitution the reader is referred to the chapter on transmitter release in the text of Kandel and colleagues.

In addition to motor nerve endings, muscle contains several types of sensory endings, all of them mechanoreceptors: free nerve endings subserve the sensation of deep pressure-pain; Ruffini and pacinian corpuscles are pressure sensors; and the Golgi tendon organs and muscle spindles are tension receptors and participate in the maintenance of muscle tone and reflex activity (page 40). The Golgi receptors are located mainly at the myotendon junctions; pacinian corpuscles are localized at the tendon site but are also found sparsely in muscle itself. Muscle spindles are specialized groups of small muscle fibers that regulate muscle contraction and relaxation, as described on page 40. All these receptors are present in highest density in muscles that are involved in fine movements.

All muscles are not equally susceptible to disease, despite the apparent similarity of their structure. In fact, practically no disease affects all muscles in the body, and each has a characteristic topography within the musculature. The topographic differences between diseases provide incontrovertible evidence of structural or physiologic differences between muscles that are not presently disclosed by the light or electron microscope, i.e., all the factors responsible for the selective vulnerability of certain muscles are not known. Several hypothetic explanations come to mind. One may relate simply to fiber size; consider, for example, the large diameter and length of the fibers of the glutei and paravertebral muscles in comparison with the smallness of the oculus motor fibers. The number of fibers composing a motor unit may also be of significance; in the oculus muscles, a motor unit contains only 6 to 10 muscle fibers (some even less), but a motor unit of the gastrocnemius contains as many as 1800 fibers. Also, the eye muscles have a much higher metabolic rate and a richer content of mitochondria than the large trunk muscles. Differences in patterns of vascular supply may permit some muscles to withstand the effects of vascular occlusion better than others. Histochemical studies of skeletal muscles have disclosed that within any one muscle, there are subtle metabolic differences between fibers—certain ones (type 1 fibers) being richer in oxidative and poorer in glycolytic enzymes, and others (type 2 fibers) being the opposite. Moreover, the distribution of certain structured proteins may alter the topography of disease expression; for example, the eye muscles do not contain dystrophin, a submembrane protein that is deficient in Duchenne and related forms of muscular dystrophy, which explains the muscles’ lack of involvement in these diseases. In addition, the endomyssial fibroblasts of eye muscles contain an abundance of glycosaminoglycans, which may render them susceptible to thyroid diseases. Diseases of the neuromuscular junction show a distribution of weakness in relation to the density of these junctions in different muscles. Doubtless other differences will be discovered.

These anatomic and biochemical properties of muscle also suggest some of the ways in which this tissue can be affected by disease. Thus, one may envisage causative agents or genetic defects that affect different components of sarcoplasm: the filamentous proteins; the mitochondrial enzymes; the sarcoplasmic reticulum; the specialized channels for the entry of calcium, sodium, or chloride; the transverse tubules; or the sarcolemma itself. Finally, the endomysial connective tissue could be the primary pathway in disease, since it so closely invests the muscle fiber.

Normal muscle is endowed with a population of embryonic muscle precursor cells, known as “satellite cells,” and as a result possesses a remarkable capacity to regenerate, a point often forgotten. It has been estimated that enough new muscle can be generated from a piece of normal muscle the size of a pencil eraser to provide normal musculature for a 70 kg adult. However, with complete destruction of the muscle fiber the regenerative capacity is greatly impaired. Destructive processes of the muscle fiber, e.g., inflammatory or metabolic, are usually followed by fairly complete restoration of the muscle cells provided that some part of each fiber has survived and the endomysial sheaths of connective tissue have not been severely disrupted. Unfortunately, many pathologic processes of muscle are chronic and unrelenting. Under such conditions, any regenerative activity fails to keep pace with the disease and the loss of muscle fibers is permanent. The bulk of the muscle is then replaced by fat and collagenous connective tissue, as typically seen in the muscular dystrophies.

**APPROACH TO THE PATIENT WITH MUSCLE DISEASE**

The number and diversity of diseases of striated muscle greatly exceed the number of symptoms and signs by which they express themselves clinically; thus, different diseases share certain common symptoms and even syndromes. To avoid excessive repetition in the description of individual diseases, we shall discuss in one place all their clinical manifestations, a subject that is appropriately called clinical myology.

The physician is initially put on the track of a myopathic disease by eliciting complaints of muscle weakness or fatigue, pain, limpness or stiffness, spasm, cramp, twitching, or a muscle mass or change in muscle volume. Of these, the symptom of weakness is by far the most frequent and at the same time the most elusive. As remarked in Chap. 24, when speaking of weakness, the patient often means excessive fatigability. Although fatigability may be a feature of muscle diseases—particularly those affecting the neuromuscular junction, such as myasthenia gravis—it is far more frequently a complaint of patients with chronic systemic disease or with anxiety and depression. Rather than relying on the patient’s report to distinguish between fatigability and weakness, it is often more informative to observe the patient during the performance of certain common activities, such as walking, running, climbing stairs, and arising from a sitting, kneeling, squatting, or reclining position. Difficulty in performing these tasks as described below signifies weakness rather than fatigue. The same is true of difficulty in working with the arms above shoulder level. Particular complaints may reveal a localized muscle weakness; e.g., drooping of the eyelids, diplopia and strabismus, change in facial expression and voice, and difficulty in chewing, closing the mouth, and swal-
lowing indicate a paresis of the levator palpebrae, extraocular, facial, laryngeal, massterter, and pharyngeal muscles, respectively. Of course, these impairments of muscle function may be due to a neuropa-thic or central nervous system (CNS) disturbance rather than to a myopathic one, but usually these conditions can be separated by the basic methods of neurology indicated further on in this chapter and in Chaps. 3 and 24.

Evaluation of Muscle Weakness and Paralysis

Reduced strength of muscle contraction—manifest by diminished power of single contractions against resistance (peak power) and during the sustained performance of prolonged or repetitive movements (i.e., endurance)—are the indubitable signs of muscle disease. In such testing, the physician may encounter difficulty in enlisting the patient’s cooperation. The tentative, hesitant performance of the asthenic or hypersuggestible individual or the hypoxic or malingerer poses difficulties that can be surmounted by the techniques described in Chap. 3. In infants and small children, who cannot follow commands, one assesses muscle power by the resistance to passive manipulation or by observing performance while the patient is engaged in certain activities. The patient may be reluctant to fully contract the muscles in a painful limb, and indeed pain itself may cause a reflex diminution in the power of contraction (algesic paresis). Estimating the strength of isometric contractions that do not require the painful part to be moved is a way around this difficulty. Sometimes the weakness of a group of muscles becomes manifest only after a period of activity; e.g., the feet and legs may “drag” only after the patient has walked a long distance. The physician, upon being told this by the patient, should attempt to conduct the examination under circumstances that duplicate the complaints.

Weakness of muscle contraction acquires added significance when it is associated with other abnormalities such as tenderness or atrophy of muscle, change in tendon reflexes, twitching, and spasm. Also, severe weakness of certain muscle groups results in abnormalities of posture and gait. A waddling gait indicates weakness of the medial glutei (or dysplasia of hip joints); excessive lumbar lordosis and protuberance of the abdomen indicate weakness of the iliopsoas and abdominal muscles; kyphoscoliosis points to an asymmetrical weakness of the paravertebral muscles; and flaring of the shoulder blades is a sign of weakness of the lower trapezi, serratus magnus, and rhomboid muscles. Equinovarus deformities of the feet may be the result of fibrous contracture (pseudocontracture) of the calf muscles.

Ascertaining the extent and severity of muscle weakness requires a systematic examination of the main groups of muscles. The patient is asked to contract each group with as much force as possible, while the examiner opposes the movement and offers a graded resistance in accordance with the degree of residual power (isokinetic contraction). Alternatively, the patient is asked to produce a maximal contraction, and the examiner estimates power by the force needed to “break” or overcome it (isometric contraction or maximum voluntary isometric contraction). If the weakness is unilateral, one has the advantage of being able to compare it with the strength on the normal side. If it is bilateral, the physician must refer to his concept of what constitutes normalcy, based on experience in muscle testing. With practice, one can distinguish true weakness from unwillingness to cooperate, feigned or neurasthenic weakness, and inhibition of movement by pain. These methods of manual muscle testing, while adequate in most clinical situations, may not be sufficiently refined for the evaluation of certain muscle diseases, particularly if serial examinations are required to determine the course of the disease and the effects of therapy.

In order to quantitate the degree of weakness, a rating scale may be required. Most widely used is the one proposed by the Medical Research Council (MRC) of Great Britain, which recognizes six grades of muscle strength, as follows:

<table>

Further gradations may be added, specified as 4+ for barely detectable weakness and 4– for easily detected weakness, 3+ and 3–, and so on. This allows for 10 gradations of power.

The ocular, facial, lingual, pharyngeal, laryngeal, cervical, shoulder, upper arm, lower arm and hand, truncal, pelvic, thigh, and lower leg and foot muscles are examined sequentially. In the case of muscle disease it is most convenient to test the same muscle from each side. The anatomic significance of each of the actions tested—i.e., what roots, nerves, and muscles are involved—can be determined by referring to Table 46-1. A practiced examiner can survey the strength of these muscle groups in 2 to 3 min. A word of caution: in manually resisting the patient’s attempts to contract the large and powerful trunk and girdle muscles, the examiner may fail to detect slight degrees of weakness, particularly in well-muscled individuals. These muscle groups are best examined by having the patient squat and kneel and then assume the erect posture, arise from and step onto a stool without using the hands, walk on his toes and heels, and lift a heavy object (e.g., Harrison’s Principles of Internal Medicine) over his head. The strength of muscles of the hand can also be quantified with a dynamometer; for research purposes, similar but more sophisticated devices exist for other muscle groups (see Fenichel et al).

Qualitative Changes in the Contractile Process

In the myasthenic states there is a rapid failure of contraction in the most affected muscles during sustained or repetitive activity. For instance, after the patient looks upward at the ceiling for a few minutes, the eyelids progressively droop; closing the eyes and resting the levator palpebrae muscles, causes the ptosis to lessen or disappear. Similarly, holding the eyes in a far lateral position will induce diplopia and strabismus. These effects, in combination with restoration of power by the administration of neostigmine or edrophonium (Tensilon), are the most valuable clinical criteria for the diagnosis of myasthenia gravis as described in Chap. 53.

In addition to myasthenic weakness, there are other abnormalities that may be discovered by observing, during one or a series of maximal actions of a group of muscles, the speed and efficiency of contraction and relaxation. In myxedema, for example, a stiffness and slowness of contraction in a muscle such as the quadriceps may be seen on change in posture (contraction myoedema); often it is associated with prolonged duration of the tendon reflexes and myoedema, which can be elicited by direct percussion of a muscle. Slowness in relaxation of muscles is another feature of hypo-
myotonic phenomenon, which typifies certain diseases—congenital myotonia (of Thomsen), myotonid dystrophy, and the paramyotonia of Eulenberg (Chap. 54). True myotonia, with its prolonged discharge of membrane action potentials, requires strong contraction to elicit, is more evident after a period of relaxation, and tends to disappear with repeated contractions (pages 1265 and 1363). Paradoxical myotonia refers to an increase in the degree of myotonia during a series of contractions (the reverse of what happens in the usual type of myotonia). It also occurs in some cases of Eulenberg paramyotonia. This persistence of contraction is demonstrable also by tapping a muscle (percussion myotonia), a phenomenon easily distinguished from the electrically silent local bulge (myoeclonia) induced by tapping the muscle of a myxedematous or cachetic patient and from the brief fascicular contraction that is induced by tapping a normal or partially denervated muscle; the latter is referred to as idiomuscular contraction. It should be noted that in patients with hyperactive tendon reflexes, striking the muscle rather than its tendon can elicit a stretch reflex.

An increment in power with a series of voluntary contractions in the absence of myotonia is a feature of the inverse myasthenic (Lambert-Eaton) syndrome, which is associated in about 50 percent of cases with small-cell carcinoma of the lung. The same increment occurs in botulism. In both instances there is an electromyographic (EMG) equivalent—a rapid increase in the voltage of a series of action potentials upon appropriate stimulation (pages 1101 and 1259).

The effect of cold on muscle contraction may also prove informative; either paresis or myotonia, lasting for a few minutes, may be evoked or enhanced by cold. This is most prominent in the paramyotonia of Eulenberg, but it may occur to some degree in all the other myotonic disorders.

Myotonia and myoeclonia must also be distinguished from the recruitment and spread of involuntary spasm induced by strong and repeated contractions of limb muscles in patients with mild or localized tetanus, with the “stiff-man” syndrome (Chap. 55), and with dystonias of various types. These are not primary muscle phenomena but are neural in origin, due to an abolition of inhibitory mechanisms.

The repeated contraction of forearm or leg muscles after the application of a tourniquet (exceeding arterial pressure) to the proximal part of a limb will often elicit latent tetany (carpopedal spasms). Its special mode of development in conditions that decrease the concentration of ionized calcium—as well as its duration, its enhancement by hyperventilation, and the association of tingling, prickling paresthesias—separate tetany from ordinary cramp and also from true physiologic contracture.

In practice, the term contracture is applied (somewhat indiscriminately, as discussed below) to all states of fixed muscle shortening. Several distinct types can be recognized. In true physiologic contracture a group of muscles, after a series of strong contractions, may remain shortened for many minutes because of failure of the metabolic mechanism necessary for relaxation; in this shortened state, the EMG remains relatively silent, in contrast to the high-voltage, rapid discharges observed with cramp, tetanus, and tetany. True contracture occurs in McArdle disease (phosphorylase deficiency), in which it is induced or aggravated by the ischemia created by a tourniquet arterial occlusion, in phosphorylase deficiency and possibly in another disease, as yet undefined, where ischemia has no effect and phosphorylase seems to be present. Yet another type of exercise-induced contracture, described originally by Brody, has been attributed by Karpati and coworkers to a deficiency of calcium adenosine triphosphatase in the sarcoplasmic reticulum. These various forms of contracture are described further in Chap. 55. True contracture needs to be distinguished from paradoxical myotonia (see earlier) and from cramp, which in certain conditions (dehydration, tetany, pathologic cramp syndrome, amyotrophic lateral sclerosis) may be initiated by one or a series of strong voluntary muscle contractions.

It is appropriate here to comment on pseudocontracture (myostatic or fibrous contracture) for which the term contracture is used in general medicine. This is the common form of muscle and tendon shortening that follows prolonged fixation and complete inactivity of the normally innervated muscle (as in a broken limb immobilized by a cast or flaccid weakness of a limb that is allowed to remain immobile). Here the shortened state of the muscle and tendons, which may persist for days or weeks, has no clearly established anatomic, physiologic, or chemical basis. Fibrosis of muscle, a state following chronic fiber loss and immobility of muscle, is another cause of muscle shortening. Depending on the predominant position, certain muscles are both weakened and shortened. Flexor fibrous contracture of the arms is a prominent feature of the Emery-Dreifuss form of muscular dystrophy. It also accounts for the rigidity and kyphoscoliosis of the spine, which are so frequently a part of myopathic diseases. The latter state is distinguished from ankylosis by the springy nature of the resistance, coincident with increased tautness of muscle and tendon during passive motion, and from Volkmann contracture, in which there is evident fibrosis of muscle and surrounding tissues due to ischemic injury, usually after a fracture of the elbow.

Arthrogryposis (multiplex congenita), described on page 1244, is another form of fibrous contracture involving multiple muscle groups. This is a syndrome of the newborn that occurs in association with several different nerve and muscle diseases that have two features in common—an onset during intrauterine life and an alteration of the neural or muscular apparatus that results in muscular weakness. In other words, contractures and fixity of the limbs in arthrogryposis are the result of immobility of the developing joints, consequent upon muscle weakness during fetal development. Most often the cause is a loss or failure of development of anterior horn cells, as in Werdnig-Hoffman disease, but the abnormality may be in the nerve roots, peripheral nerves, or motor end plates, which paralyzes groups of muscles, or in the muscle itself. The rigid spine syndrome in children is yet another form of fibrous contracture, due presumably to an unusual axial muscular dystrophy.

Topography or Patterns of Myopathic Weakness

In almost all the diseases under consideration, some muscles are affected and others spared, each disease displaying its own pattern.
Restated, the topography or distribution of involvement tends to be alike in all patients with the same disease. Thus, the pattern of weakness is a central diagnostic attribute of muscular disease as it is for the various diseases of the peripheral nervous system discussed in Chap. 46, but the configurations differ in important ways between disease of the muscles and of the nerves.

The following patterns of muscle involvement constitute a core of essential clinical knowledge in this field:

1. **Ocular palsies presenting more or less exclusively as ptosis, diplopia, and strabismus.** As a rule, primary diseases of muscle do not involve the pupil, and in most instances their effects are bilateral. In lesions of the third, fourth, or sixth cranial nerves, the neural origin is disclosed by the pattern of ocular muscle palsies, abnormalities of the pupil, or both. When weakness of the orbicularis oculi (muscles of eye closure) is added to weakness of eye opening (levator palpebrae; ptosis), it nearly always signifies myasthenia gravis and occasionally, a rare primary disease of muscle (progressive external ophthalmoplegia).

   The most frequent causes of *subacute and chronic* development of *relatively pure* affection of the muscles of eye movement are myasthenia gravis, progressive external ophthalmoplegia, oculopharyngeal muscular dystrophy, and exophthalmic (hyperthyroid) ophthalmoplephy. In progressive external ophthalmoplegia, the muscles including the levators of the eyelids become paralyzed almost symmetrically over a period of years. This disorder has been shown in most cases to be a form of mitochondrial myopathy at times coupled with the Kearns-Sayre syndrome noted further on. Oculopharyngeal dystrophy involves primarily the levators of the eyelids and, to a somewhat lesser extent, other eye muscles and pharyngeal-upper esophageal striated muscles. It begins in middle or late adult life and later, and—like progressive external ophthalmoplegia—tends later to involve girdle and proximal limb muscles.

   There are several other less common chronic myopathies in which external ophthalmoplegia is associated with involvement of other muscles or organs, namely, the congenital ophthalmoplegia of the Goldenhar-Gorlin syndrome (see Aleksic et al); the Kearns-Sayre syndrome (retinitis pigmentosa, heart block, short stature, generalized weakness, and ovarian hypoplasia); other congenital myotubular and mitochondrial myopathies; nuclear ophthalmoplegia with bifacial weakness (Möbius syndrome); and the myotonic dystrophy of Steinert. Rarely, eye muscle weakness may occur at a late stage in other dystrophies, such as the facioscapulohumeral type. Although not a regular feature of the disease, ophthalmoparesis can occur in the “reverse myasthenic” syndrome of Lambert-Eaton.

   **Acute bilateral ophthalmoplegia** raises an entirely different set of diagnostic considerations. It may be an expression of the Fisher syndrome that consists of ophthalmoplegia, areflexia, and ataxia and of other variants of the Guillain-Barré syndrome, or of botulism, diphtheria, rarely tick paralysis, and of occlusion of the basilar artery or its branches.

   Ptosis is variable in all of these conditions. When present in infantile myopathic disease, it is frequently a marker of the congenital myasthenic syndromes. Trichinosis is a rare cause, associated also with periorbital edema.

2. **Bifacial palsy presenting as an inability to smile, to expose the teeth, and to close the eyes.** Varying degrees of bifacial weakness are observed in myasthenia gravis, usually conjoined with ptosis and ocular palsies. However, weakness of facial muscles may on occasion be combined with myasthenic weakness of the masseters and other bulbar muscles without involvement of ocular muscles. Facial weakness and ptosis are features of myotonic dystrophy. More severe or complete facial palsy occurs in facioscapulohumeral dystrophy, sometimes presenting several years before weakness of the shoulder girdle muscles. Bifacial weakness is also a feature of certain congenital myopathies (centronuclear, nemaline, carnitine deficiency), Kennedy type of degenerative bulbo-bulbospinal atrophy (prominent facial fasciculations), and the Möbius syndrome (in combination with abducens palsies).

   More acute and *subacute* bifacial palsies are usually attributable to the Guillain-Barré syndrome, sarcoidosis, Lyme disease, tick paralysis, Melkerson-Rosenthal syndrome, AIDS, polymyositis (rare), neoplastic infiltration, or are part of a cranial polyneuritis of unknown cause, all of which have been discussed in preceding chapters. Rarely, “idiopathic” Bell’s palsy is simultaneously bilateral (it is more often segmental). Advanced scleroderma, Parkinson disease, or a pseudobulbar state can immobilize the face to the point of simulating myopathic or neuropathic paralysis, but always in a context that makes the cause obvious.

3. **Bulbar (oropharyngeal) palsy presenting as dysphonia, dysarthria, and dysphagia or without weakness of jaw or facial muscles.** Myasthenia gravis is the most frequent cause of this syndrome and must also be considered whenever a patient presents with the solitary finding of a hanging jaw or fatigue of the jaw while eating or talking; usually, however, ptosis and ocular palsies are conjoined. Dysphagia and dysphonia may be early and prominent signs of polymyositis as well as inclusion body myositis and may appear in patients with myotonic dystrophy, due to upper esophageal atonia.

   Combinations of these palsies are also observed as an *acute syndrome* in botulism, in brainstem stroke, and at the outset of the Guillain-Barré syndrome. Diphtheria and bulbar poliomyelitis are now rare diseases that may present in this way. Progressive bulbar palsy (motor neuron disease) may be the basis of this syndrome (page 940); the diagnosis is most obvious when the tongue is withered and twitching. Syringobulbia, basilar invagination of the skull, and certain types of Chiari malformation may reproduce some of the findings of bulbar palsy by involving the lower cranial nerves. Rare cases of hereditary progressive aphonia include the earlier mentioned X-linked Kennedy syndrome of bulbo-bulbospinal atrophy (page 947).

   Spastic bulbar paralysis, or pseudobulbar palsy, is readily distinguished by the presence of hyperactive facial and gag reflexes, lack of muscle atrophy, and the associated clinical findings (pages 426 and 450). One must also keep in mind restricted extrapyramidal diseases, such as Wilson disease and dystonias, that cause the mouth to be kept open and the face and bulbar musculature to appear immobile. The mechanism of swallowing and the ways in which it is disturbed are discussed in Chap. 26.

4. **Cervical palsy presenting with inability to hold the head
erect or to lift the head from the pillow ("hanging, or dropped, head" syndrome, "camptocormia"). This is due to weakness of the posterior neck muscles and of the sternocleidomastoids and other anterior neck muscles. In advanced forms of this syndrome the head may hang with chin on chest unless the patient holds it up with his hands. There may be difficulty differentiating the condition from a dystonic anterocollis; in the latter there is palpable tonic spasm of the sternomastoid and posterior neck muscles.

This topographic pattern occurs most often in idiopathic polymyositis and inclusion body myositis in which case it is often combined with mild dysphagia, dysphonia, and weakness of girdle muscles. The same symptom may be a feature of motor neuron disease and is infrequently the presenting feature. Myasthenic patients commonly complain of an inability to hold up their heads late in the day; both flexors and extensors of the neck are found to be weak. Occasionally this pattern is observed in patients with nemaline rod myopathy.

There is in addition, a poorly defined local myopathic process of the cervical paraspinal muscles that has no distinguishing histopathologic or histochemical features and has accounted for many of the cases of neck extensor weakness that we have encountered. The latter condition is observed in elderly persons, mainly men. There is severe but relatively nonprogressive weakness of the neck extensors and only mild weakness of shoulder girdle and proximal arm muscles. Katz and colleagues suggest the designation "isolated neck extensor myopathy" in preference to dropped head syndrome. What has been referred to as a "hent spine" syndrome (for which the term camptocormia has also been used) is probably the same entity and may follow after years of the condition affecting the neck, or it may surface independently. These conditions of cervical weakness are reviewed by Umapathi and colleagues.

The major types of progressive muscular dystrophy, when advanced, usually affect the anterior neck muscles severely. Syringomyelia, spinal accessory neuropathy, some form of meningoaracditis, and loss of anterior horn cells in conjunction with systemic lymphoma or carcinoma may differentially paralyze the various neck muscles.

5. Weakness of respiratory and trunk muscles. Usually the diaphragm, chest, and trunk muscles are affected in association with shoulder and proximal limb muscles, but occasionally weakness of the respiratory muscles is the initial or the dominant manifestation of muscle disease. Selective involvement of the intercostal muscles and diaphragm, giving rise to dyspnea and diminished vital capacity usually first brings the patient to the pulmonary clinic. The main causes are motor neuron disease, polymyositis, myasthenia, and, far less often because of their rarity, glycogen storage disease (acid maltase deficiency) and congenital nemaline myopathy. Unilateral paralysis of the diaphragm may result from compression of the phrenic nerve in the thorax by tumor or aortic aneurysm; an idiopathic or postinfectious variety may be related to brachial plexitis (page 1165). The paravertebral muscles may be severely affected in some types of muscular dystrophy, but usually in association with pelvicural and shoulder muscle weakness. Nocturnal dyspnea, sleep apnea, and respiratory arrest may occur, particularly in myasthenics and patients with glycogen storage myopathies. And, of course, respiratory failure may threaten life in severe myasthenia gravis and Guillain-Barré syndrome, as it can in poliomyelitis.

As a general rule, in the acute neuromuscular paralyses, the cervical and shoulder muscles and the diaphragm, all of which share a common innervation, show a similar degree of weakness. Asking the patient to count aloud a consecutive series of numbers on one maximal breath can help to detect this pattern of muscle weakness (less than 20 equates with a vital capacity at or below about 2 L). Paradoxical inward movement of the abdomen with inspiration is another sign of diaphragmatic weakness. Disorders of breathing and ventilation are discussed in Chap. 26 and in Chap. 46 in relation to Guillain-Barré syndrome.

6. Bibrachial palsy and the dangling-arm syndrome. Weakness, atrophy, and fasciculations of the hands, arms, and shoulders characterize the common form of motor neuron disease, namely, amyotrophic lateral sclerosis. Primary diseases of muscle hardly ever weaken these parts disproportionately. Rarely, a diffuse weakness of both arms and the shoulder muscles may occur in the early stages of Guillain-Barré syndrome, paraneoplastic disease, and amyloid polyneuropathy, in special forms of IgM-related paraproteinemic, or in inflammatory polyneuropathy (e.g., brachial neuritis), and in porphyric polyneuropathy. A lesion affecting the central portion of the spinal cord in the cervical region produces this same pattern, but then in association with loss of pain and thermal sensation in the upper limbs and shoulders, a problem that excludes disease of muscle. Trauma and infarction of the cord are the usual causes of this type of myelopathy (we have seen two cases attributable to multiple sclerosis but this is most uncommon).

7. Proximal limb-girdle palsies presenting as inability to raise the arms or to arise from a squatting, kneeling, or sitting position. Polymyositis, inclusion body myositis, dermatomyositis, and the progressive muscular dystrophies most often manifest themselves in this fashion. The endocrine and the acquired metabolic myopathies (e.g., Cushing disease, hyperthyroidism, and steroid or statin administration) are also common causes. Proximal limb weakness is a common feature of myasthenia but almost always after the development of ocular or pharyngeal involvement. The childhood Duchenne, Becker, and limb-girdle types of dystrophy tend first to affect the muscles of the pelvic girdle, gluteal region, and thighs, resulting in a lumbar lordosis and protuberant abdomen, a waddling gait, and difficulty in arising from the floor and climbing stairs without the assistance of the arms. Facioscapulohumeral dystrophy affects the muscles of the face and shoulder girdles foremost and is manifest by incomplete eye closure, inability to whistle and to raise the arms above the head, winking of the scapulae, and thinness of the upper arms with preserved forearm bulk ("Popeye" effect). Certain early or mild forms of dystrophy may selectively involve only the peroneal and scapular muscles (scapuloperoneal dystrophy). In the milder forms of polymyositis, weakness may be limited to the neck muscles or those of the shoulder or pelvic girdles.

A number of other diseases of muscle may express themselves by a disproportionate weakness of girdle and proximal limb musculature. An intrinsic metabolic myopathy, such as the adult form of acid maltase deficiency and
the familial (hypokalemic) type of periodic paralysis, may affect only the pelvic and thigh muscles. In a number of the congenital polymyopathies (central core, nemaline, myotubular, etc.), a relatively nonprogressive weakness affects girdle muscles more than distal ones. These are discussed in Chap. 52. Proximal muscles are occasionally implicated in progressive spinal muscular atrophy, as in the syndrome first described by Wohlfart and coworkers and by Kugelberg and Welander, which unfortunately adds to confusion in diagnosis.

8. **Bicrural palsy** presenting as lower leg weakness with inability to walk on the heels and toes, or as **paralysis of all leg muscles**. With the exception of rare but distinctive distal types of muscular dystrophy, this pattern is not due to myopathy. Symmetrical weakness of the lower legs is usually due to polyneuropathy, although peroneal, anterior tibial, and thigh muscles are often weakened in muscular dystrophy. Diabetic polyneuropathy or carcinomatous or lymphomatous radiculopathy may cause asymmetrical weakness of thigh and pelvic muscles, often with pain and little sensory change. Chronic inflammatory demyelinating polyneuropathy (CIDP) may do the same. In total leg and thigh weakness, one, of course, considers a spinal cord disease, in which case there is usually impaired sphincteric function of the bladder and bowel as well as loss of sensory perception below a certain level on the trunk. Motor system disease may begin in the legs, asymmetrically and distally as a rule, and affect them out of proportion to other parts. Thus the differential diagnosis of distal or generalized leg weakness involves more diseases than are involved in the restricted paralyses of other parts of the body.

A **pure quadriceps femoris weakness** may be the expression of several diseases. If bilateral, it usually indicates a polymyositis, an early stage of inclusion body myositis (where it may also be unilateral or asymmetrical), or a restricted dystrophy. In thyrotoxic and steroid myopathies, the major effects are on the quadriceps muscles. If unilateral or bilateral with loss of patellar reflex and sensation over the inner leg, this condition is due most often to a femoral neuropathy, as occurs from diabetes, or to an upper lumbosacral plexus lesion. Injuries to the hip and knee cause rapid disuse atrophy of the quadriceps muscles. A painful condition of infarction of this muscle is seen in diabetic patients.

9. **Distal bilateral limb palsies presenting usually as foot drop with steppage gait (with or without pes cavus), weakness of all lower leg muscles, and later wrist drop and weakness of hands.** The principal cause of this syndrome is a familial polyneuropathy, mainly the group of peroneal muscular atrophies of Charcot-Marie-Tooth type or the hypertrophic polyneuropathy of Déjerine and Sottas (see Chap. 46). Chronic nonfamilial polyneuropathies, particularly paraproteineemic and inflammatory ones with motor conduction block and exceptionally some forms of familial progressive muscular atrophy and distal types of progressive muscular dystrophy (Gowers, Milhorat, Welander, and Miyoshi types) may also present in this way. In myotonic dystrophy, there may be weakness of the leg muscles as well as the forearms, sternocleidomastoids, face, and eyes. With these exceptions, the generalization that **girdle weakness without sensory changes is indicative of myopathy and that distal weakness is indicative of neuropathy** is clinically useful.

10. **Generalized or universal paralysis** of limb (but usually not cranial) muscles, involved either in attacks or as part of a chronic persistent, progressive deterioration. When acute in onset and episodic, this syndrome is usually a manifestation of familial hypokalemic or hyperkalemic periodic paralysis. One variety of the hypokalemic type is associated with hyperthyroidism, another with hyperaldosteronism (Chap. 54). Attacks of porphyric neuropathy and of Refsum disease have an episodic nature. Generalized paresis (rather than paralysis) that has an acute onset and lasts many weeks is at times a feature of a severe form of idiopathic or parasitic (trichinosis) polymyositis and rarely of the toxic effects of certain pharmaceutical agents, particularly those used to treat hypercholesterolemia. Idiopathic polymyositis and rarely inclusion body myositis may involve all limb and trunk muscles but usually spare the facial and ocular muscles, whereas the weakness in trichinosis is mainly in the ocular and lingual muscles. In infants and young children, a chronic and persistent generalized weakness of all muscles except those of the eyes always raises the question of Werdnig-Hoffman spinal muscular atrophy or, if mild in degree and relatively nonprogressive, of congenital myopathy or polyneuropathy. In these diseases of infancy, paucity of movement, hypotonia, and retardation of motor development may be more obvious than weakness. Arthrogryposis may be present at birth. As a rule, universal weakness of muscle does not occur in the muscular dystrophies.

Widespread **ascending paralysis** (progressing from the arms to the legs), developing over a few days, with involvement of cranial (including ocular) muscles, is usually due to an inflammatory demyelinating or axonal polyneuritis (Guillain-Barré syndrome) and occasionally to porphyric or diphtheric polyneuropathy, tick paralysis, or severe hypophosphatemia. In a setting of a critical illness with multiple organ failure or sepsis, generalized weakness of variable degree may occur from either a neuropathy (“critical illness” neuropathy) or a severe and widespread myopathy that is thought to be caused by the use of high doses of corticosteroids, especially if there has been concomitant use of neuromuscular blocking agents. Certain generalized neuropathies evolve subacutely, and this may also be true in patients undergoing peritoneal dialysis for end-stage renal failure or with toxic exposure to certain heavy metals. An even more insidious onset and slow (months to years) progression of paralysis, atrophy, and fasciculation of limb and trunk muscles without sensory loss characterize motor system disease. Here the eye muscles are always spared. The Lambert-Eaton syndrome may cause a similar picture.

11. **Paralysis of single muscles or a group of muscles.** This is usually neuropathic, less often spinal or myopathic. Muscle disease does not need to be considered except possibly in certain instances of pressure-ischemic necrosis of muscle due to local pressure or infarction, as in so-called monoplegic alcoholic myopathy or in diabetic muscle infarction. Also, the weakness of inclusion body myositis has a preference for certain sites, specifically parts of the quadriceps, or of the forearm muscles, particularly the long finger flexors (flexor digitorum profundus).

From this exposition of the topographic aspects of weakness, one can appreciate that each neuromuscular disease exhibits a pred-
ilection for particular groups of muscles. Apart from these topographic patterns that suggest certain possibilities of disease and exclude others, diagnosis depends on additional features—the age of the patient at the time of onset and tempo of progression, the coexistence of medical disorders, and certain laboratory findings (serum concentrations of muscle enzymes, EMG, and biopsy findings) and genetic determinants also figure prominently in the delineation of muscle diseases.

**Muscle Tone**

All normal muscles display a slight resistance to stretch even when fully relaxed. When stretched to their limit and released, they recoil, mainly because of the elasticity of the fibers and their connective tissue sheaths. In addition, the trunk and proximal limb musculature is intermittently or constantly activated in the maintenance of attitudes and postures. To relax—i.e., to completely disengage a muscle from all its natural activities—requires practice and seems increasingly difficult in the elderly, in whom it merges with oppositional, or paratonic, rigidity (“gegenhalten,” page 63).

A reduced innervation of muscle, atrophy, or loss of contracting fibers are causes of “hypotonia.” In infants this state has come to be accepted as a mark of neuromuscular disease; the infant is said to be “floppy.” For this reason, the assessment of muscle tone is of special importance in infants (the floppy baby), but the testing of strength at this age is difficult. Tone can be assessed by lifting the infant in a prone position; if the child is hypotonic, the head and leg cannot be supported against gravity and, therefore, dangle. Or, when held under the arms, the hypotonic infant slips through and legscannot besupportedagainst gravity and, therefore, dangle. The finding of generalized excessive tone, apart from that observed as a consequence of extrapyramidal rigidity, is rare in infants. A purely myopathic form of hypertonia is difficult to substantiate (the exception being hypocalcemic tetany). Various types of disease may lead to fibrous contracture and arthrogryposis, as stated earlier. An axial myopathy is the basis of the rigid spine syndrome, as mentioned earlier. For the most part, the muscle stiffness syndromes are due to continuous overactivity of motor units, the extreme forms being the stiff-man and the Isaacs syndromes and several related conditions (Chap. 55).

**Muscle Fatigue, Lack of Endurance, and Exercise Intolerance**

As stated earlier in this chapter and in Chap. 24, fatigue is an abstruse symptom, always requiring analysis and interpretation. When not attended by manifest reduction in muscle power, it is usually nonmuscular in origin. It may, on medical investigation, prove to be a systemic manifestation of infection, metabolic or endocrine disorder, severe anemia, reduced cardiopulmonary function, or neoplasia. More often, when expressed as a feeling of poor endurance, weariness, and disinclination to undertake or sustain mental and physical activity, it is indicative of neurasthenia, a psychiatric manifestation common to states of chronic anxiety and depression or simply to boredom and lack of purpose. An elusive syndrome of lifelong exercise intolerance, often accompanied by muscle cramps during exercise, has been traced in a limited number of cases to mutations in the cytochrome b gene of the mitochondrial DNA (Andreu et al), and similar syndromes have been attributed to a deficiency of myoadenylate—but these are both rare. The subject of fatigue as a physiologic phenomenon and as a clinical feature of many psychiatric and medical diseases, including those that are predominantly myopathic, is considered fully in Chap. 24.

**Changes in Muscle Volume**

Diminution or increase in muscle bulk stands as another feature of disease that can be observed in all except the most obese patients. There are, of course, innate differences in muscle development, a greater salience of muscle in the male than in the female, and differences due to use and disuse. In general, the relative size of muscles is a genetic trait; in some families, muscles, like the skeleton, are large and in others, small. Greatly increased size and strength of muscles (hypertrophia musculorum vera) is an inherited trait caused by a mutation in the myostatin gene. It also is observed in cultists devoted to bodybuilding (although, as a rule, they are exercising muscles that are large from birth); in congenital myotonia (circuit freaks with phenomenal muscular development often have this condition); in instances of a rare pathologic cramp syndrome; in the Bruck-De Lange syndrome of congenital hypertrophy of muscle, athetosis, and mental retardation; and in some patients destined to develop muscular dystrophy. In some of the latter patients, the muscle enlargement is in reality a pseudohypertrophy, in which the increase in size is accompanied by weakness. Here large and small fibers are mixed with fat cells, which have replaced many of the degenerated muscle fibers; other muscles in the same patient are atrophied. Other dystrophies (Becker, Emery-Dreifuss) may also cause pseudohypertrophy. Rarely, we have seen it in amyloidosis, sarcoidosis, eosinophilic myositis, and certain of the congenital myopathies. Hypothyroidism is often accompanied by an increase in volume of certain muscles, at times pronounced enough to simulate the hypertrophia musculorum vera. Enlargement of muscles in only one limb may be due to an arteriovenous malformation, neurofibroma, or the Klippel-Trénaunay-Weber syndrome involving the nerve root. A single muscle may become hypertrophied after partial injury to its nerve root (see Mielke et al); this is seen most often in relation to disc compression or surgical injury of the S1 nerve root.

Denervation is almost invariably attended by atrophy. Lesions of the peripheral nerve or anterior horn cells, if complete, lead to a loss of bulk of up to 85 percent of the original volume within 3 to 4 months, although some shrinkage of muscle becomes evident before that time. The most severe degrees of atrophy are observed in the chronic polyneuropathies, motor system diseases, and muscular dystrophies. The distribution of the atrophy corresponds to the paresis. (There are rare and unexplained instances where muscle hypertrophy follows denervation.) Cachexia, malnutrition, male hypogonadism, panhypopituitarism, and lipodystrophy tend to reduce muscle bulk without a proportionate reduction in the power of contraction (pseudoaatrophy). Of interest is the fact that a number of myopathic diseases result in severe weakness with little or no adults, hypotonia is a feature of many of the myopathies and neuropathies, all of which reduce the number of contracting motor units.
atrophic; these are polymyositis, myasthenia gravis, periodic paralyses, steroid myopathy, hypothyroidism, and Addison disease.

**Twitches, Spasms, and Cramps**

Fascicular twitches of muscle at rest (fasciculations), if pronounced and combined with muscular weakness and atrophy, usually signify motor neuron disease (amyotrophic lateral sclerosis, progressive muscular atrophy, or progressive bulbar palsy); but they may be seen in other diseases that involve the gray matter of the spinal cord (e.g., syringomyelia or tumor) as well as in lesions of the anterior roots (e.g., protruded intervertebral disc) and in certain peripheral neuropathies. Widespread fasciculations may occur acutely with severe dehydration and electrolyte imbalance after an overdose of neostigmine or with organophosphate poisoning. Slow and persistent fasciculations, spreading in a wave-like pattern along the entire length of a muscle and associated with slight reduction in the speed of contraction and relaxation, are part of the syndrome of continuous muscular activity (page 1278). Fasciculations that occur with muscular contraction, in contrast to those at rest, indicate a state of heightened irritability of muscle; this may occur for no discernible reason or as a sequel of denervation that leaves muscle with some paralyzed motor units, so that during contraction small and increasingly larger units are not enlisted smoothly. Fasciculations of the facial muscles are typical of the Kennedy type of bulbospinal atrophy.

Benign fasciculations, a common finding in otherwise normal individuals, can be identified by the lack of muscular weakness and atrophy and by the smallness of the muscle fascicle involved and repetitive appearance in only one or two regions. The recurrent twitches of the eyelid or muscles of the thumb experienced by most normal persons, is the universalis. Notably, few of the primary muscular dystrophies are painful, when cramps are provoked by the abrupt stretching of muscles, are very painful, and tend to wax and wane before they disappear. The EMG counterpart is a high-frequency discharge. Although of no pathologic significance, the cramps in extreme cases are so persistent and so readily provoked by innocuous movements as to be disabling. Cramps of all types need to be distinguished from sensations of cramp without muscle spasm. The latter is a dysesthetic phenomenon in certain polyneuropathies.

Contrasted to cramp is the physiologic contracture, observed in McArdle disease and carnitine palmityl transferase deficiency, in which increasing muscle shortening and pain gradually develop during muscular activity. Unlike cramping, it does not occur at rest, the pain is less intense, and the EMG of the contracted muscle at the time is relatively silent.

Cramps are also to be distinguished from the disabling and progressive form of painful spasm of the axial and proximal muscles known as the already mentioned stiff-man syndrome; this appears to be a disease of the spinal interneurons (page 1279). Continuous spasm intensified by the action of muscles and with no demonstrable disorder at a neuromuscular level is a common manifestation of localized tetanus and also follows the bite of the black widow spider. These disorders must be differentiated from a rare but distinctive type of encephalomyelitis of unknown cause ("spinal neuronitis"), characterized by intense rigidity and myoclonic jerking of trunk and limbs and painful spasms evoked by tactile and other stimuli. The damage in this disease is thought to be mainly to spinal interneuronal neurons, with disinhibition of anterior horn cells (Howell et al; see also page 1067). There may also be difficulty distinguishing cramps and spasms from the early stages of a dystonic illness and from tetanus.

All the aforementioned phenomena of cramping and pathologic activity of muscle fibers are elaborated in Chap. 55.

**Palpable Abnormalities of Muscle**

Altered structure and function of muscle are not accurately revealed by palpation. Of course, the difference between the firm, hypertrophied muscle of a well-conditioned athlete and the slack muscle of a sedentary person is as apparent to the palpating fingers as to the eye, as is also the persistent contraction in tetanus, cramp, contracture, fibrosis, and extrapyramidal rigidity. The muscles in dystrophy are said to have a "doughy" or "elastic" feel, but we find this difficult to judge. In the Pompe type of glycogen storage disease, attention may be attracted to the musculature by an unnatural firmness and increase in bulk. The swollen, edematous, weak muscles in acute rhabdomyolysis with myoglobinuria or severe polymyositis may feel taut and firm but are usually not tender. Areas of tenderness in muscles that otherwise function normally, a state called myoglobinosis, have been attributed to fibrosis or fibromyositis, but their nature has not been divulged by biopsy.

A tumorous or granulomatous mass may develop in part of a muscle or throughout a muscle, posing a series of special clinical problems discussed on page 1282.

**Muscle Pain**

Notably, few of the primary muscle diseases are painful. When pain is prominent and continuous during rest and activity, there will usually be evidence of disease of the peripheral nerves, as in al-
Adulthood neurologic and muscular diseases may be a feature of several conditions, including Alzheimer disease, Down syndrome, myoclonus, and parkinsonism. These conditions may be associated with various degenerative or inflammatory changes in the CNS, peripheral nervous system, and muscles. The clinical manifestations of these conditions may vary widely and can include muscle weakness, atrophy, and dystrophy; dysarthria; mental retardation; seizures; and other neurologic symptoms. Some of these conditions may be familial or associated with specific genetic disorders.

The diagnosis of AMDM includes a careful history and physical examination, laboratory tests, and imaging studies. Imaging studies may include magnetic resonance imaging (MRI), computed tomography (CT), or ultrasound. Laboratory tests may include blood tests to assess for anemia, electrolyte abnormalities, and infection. Imaging studies may help to identify the site and extent of muscle involvement. Laboratory tests may help to identify the underlying cause of muscle weakness or atrophy. The diagnosis of AMDM may be challenging, and it may require a multidisciplinary approach involving neurologists, internists, and other specialists.

The management of AMDM includes symptomatic treatment and targeted therapy. Symptomatic treatment may include physical therapy, occupational therapy, and assistive devices. Targeted therapy may include medications, surgery, and other interventions. The goals of treatment are to improve muscle function, reduce pain and discomfort, and improve quality of life. The management of AMDM is individualized and may require a long-term approach.

In conclusion, AMDM is a complex and heterogeneous group of conditions that may involve multiple organ systems. The diagnosis and management of AMDM requires a multidisciplinary approach and individualization of care. Further research is needed to better understand the underlying causes of these conditions and to develop new therapies.
In summary, the clinical recognition of myopathic diseases is facilitated by a prior knowledge of a few syndromes, of the age of the patient at the onset of the illness, of a familial occurrence of the same or similar illnesses, and of the medical setting in which weakness evolves. A description of these syndromes and the diseases of which they are manifestations forms the content of the chapters that follow. Diagnostic accuracy is aided by the intelligent use of the laboratory examinations discussed in Chap. 45, particularly the muscle enzymes, electromyogram, and muscle biopsy.

CHAPTER 49
THE INFLAMMATORY MYOPATHIES

The discovery that striated skeletal muscle and cardiac muscle could be the sole targets of a number of infectious diseases came about during the era of the development of microbiology and occupied the attention of many prominent clinicians, including Osler. As these diseases were being characterized, however, a number of other inflammatory states affecting muscle were found for which there was no infectious cause. Later, an autoimmune mechanism was postulated, but even today this is not securely established. This group of idiopathic inflammatory myopathies figures so prominently in clinical myology that the authors feel justified in devoting a chapter to the subject. But first, the infections of muscle are described.

THE INFECTIVE FORMS OF POLYMYOSITIS

Included here are trichinosis, toxoplasmosis, parasitic and fungal infections, and a number of viral infections. The related but unclassifiable entity of sarcoid myopathy is addressed at the end of the chapter.

Trichinosis

This parasitic disease is caused by the nematode Trichinella spiralis. Its general features have been discussed in Chap. 32 (page 625). With respect to the myopathic aspect of the illness, the authors have been most impressed with the ocular muscle weakness, which results in strabismus and diplopia; with weakness of the tongue, resulting in dysarthria; and with weakness of the masseter and pharyngeal muscles, which interferes with chewing and swallowing. Any weakness of limb muscles is usually mild and more severe proximally than distally. However, the diaphragm may be involved, as well as the myocardium. The affected muscles are slightly swollen and tender in the acute stage of the disease. Often, there is conjunctival, orbital, and facial edema, sometimes accompanied by subconjunctival and subungual splinter hemorrhages. As the trichinae become encysted over a period of a few weeks, the symptoms subside and recovery is complete. Many, perhaps the majority, of infected patients are asymptomatic throughout the invasive period, and as much as 1 to 3 percent of the population in certain regions of the country will be found at autopsy to have calcified trichinella cysts in their muscles with no history of parasitic illness. Heavy infestations have been known to end fatally, usually from cardiac and diaphragmatic involvement. In these more massive infections, the brain also may be involved, probably by emboli that arise in the heart from an associated myocarditis.

Diagnosis Clinically, one should suspect the disease in a patient who presents with a puffy face and tender muscles. Eosinophilia is practically always present in the peripheral blood (>700 cells per cubic millimeter), although the sedimentation rate is often normal. The creatine kinase (CK) level is moderately elevated. A skin test using Trichinella antigen is available but it is unreliable. The enzyme-linked immunosorbent assay (ELISA) blood test is more accurate but it becomes positive only after 1 or 2 weeks of illness. Biopsy of almost any muscle (usually the deltoid or gastrocnemius), regardless of whether it is painful or tender, is probably the most reliable confirmatory test. More than 500 mg of muscle may be required to demonstrate larvae, but smaller specimens will almost invariably show an inflammatory myopathy. Muscle fibers undergo segmental necrosis, and the interstitial inflammatory infiltrates contain a predominance of eosinophils. This accounts for the edema, pain, and tenderness of heavily infested muscles. The capsules of the larvae gradually thicken in the first month of the infection, and then calcify. The electromyogram (EMG) may exhibit profuse fibrillation potentials, a phenomenon attributed on theoretical grounds to the disconnection of segments of muscle fibers from their motor end plates (Gross and Ochoa).

Treatment No treatment is required in most cases. In patients with severe weakness and pain, a combination of thiabendazole 25 to 50 mg/kg daily in divided doses for 5 to 10 days and prednisone 40 to 60 mg/day is recommended. Albendazole, in a single oral dose of 400 mg daily, is equally effective but is not available in the United States except by special request (from Smith Kline Beecham).

Recovery, as mentioned, is complete as a rule except in rare patients with cerebral infarcts. Other aspects of this infestation are discussed in Chap. 32.

Toxoplasmosis

This is an acute to subacute systemic infection due to the encephalitozoon Toxoplasma gondii. Most Toxoplasma infections in immunocompetent patients, which occur in up to 10 to 30 percent of the population, are asymptomatic, but there may be fever and varying degrees of involvement of the skin, lymph nodes, retina, myocardium, liver, brain, and muscle. In one such case, Toxoplasma organisms and pseudocysts were detected in skeletal muscle (Kass and Adams); wherever a parasitic pseudocyst had ruptured, there was focal inflammation. Some muscle fibers had undergone segmental necrosis, but this was not prominent (one contained the organism), accounting for the relative paucity of muscle symptoms. With the introduction of acquired immunodeficiency syndrome (AIDS), many more toxoplasmic infections, including those of skeletal muscle, are seen (Gherardi et al). However, physicians who see many cases of AIDS have indicated to us that a primary AIDS myopathy and treatment-related muscle diseases are more common (see later). Also in this population, brain infestation with Toxoplasma is many times more common than myositis.

The myopathy, which occurs in the context of fever, lymphopenia, and failure of other organs, consists of weakness, wasting, myalgias, and elevated CK levels. Presumably, the immunocompromised patient is unable to respond to protozoan infections, and...
latent infections are reactivated. Sulfadiazine in combination with pyrimethamine or trimethoprim-sulfamethoxazole, which act synergistically against the toxoplasma trophozoites, improves the muscle symptoms and reduces serum CK. Folic acid must be given in addition. The subject of AIDS and toxoplasma infection is discussed more fully on pages 623 and 644.

Other Parasitic and Fungal Infections of Muscle

Echinococcosis, cysticercosis, trypanosomiasis (Chagas disease), sparganosis, toxocariasis, and actinomycosis have all been known to affect skeletal muscle on occasion, but the major symptoms relate more to involvement of other organs. Only cysticercosis may first claim the attention of the clinical myologist because of a dramatic pseudohypertrophy of thigh and calf muscles. Hydatids infest the paravertebral and lumbar girdle muscles in 5 percent of cases and may lead to their enlargement. Coenurosis and sparganosis are causes of movable lumps in the rectus abdominis, thigh, calf, and pectoralis muscles. Protozoan infections of muscle—microsporidiosis, African and American trypanosomiasis—which occurred only rarely until a decade ago, are now being observed in immunodeficient (HIV-infected) individuals in endemic areas. The reader who seeks more details may refer to the chapter on parasitic myositis by Banker.

Viral Infections of Muscle

**HIV and HTLV-I Myositis** Human immunodeficiency virus (HIV) and human T-lymphotropic virus type I (HTLV-I) have become increasingly common causes of viral myositis (Engel and Emile-Smith). Moreover, it is widely believed that zidovudine (ZVD), a drug included in most regimens to treat HIV infections, may itself induce an inflammatory myopathy with myalgia and weakness (Dalakas et al). The frequency of this particular drug-induced myopathy is not altogether certain; in a one large multicenter trial of antiretroviral drugs there was no increase in myopathy in patients who were treated with ZVD or any other drug in its class (Simpson et al).

An inflammatory, and presumed infectious, myopathy (a polymyositis) can develop early in the course of HIV infection and may rarely be the initial manifestation. The pattern is like that of idiopathic polymyositis with painless weakness of the girdle and proximal limb muscles. Reflexes are diminished in most cases, but this is difficult to interpret in view of the high incidence of concomitant polyneuropathy. Serum CK is elevated and the EMG shows an active myopathy with fibrillations, brief polyphasic motor units, and complex repetitive discharges.

The myopathologic changes in AIDS are also like those of idiopathic polymyositis. Additionally, in some cases, electron microscopy discloses the presence of nemaline (rod) bodies within type 1 fibers, similar to those observed in the congenital form of nemaline of polymyopathy (page 1247). As implied earlier, the pathogenesis of the AIDS myopathy has not been firmly established since there is as yet scant evidence of a direct viral infection of the muscle fibers. An immune basis has been suggested in view of a response to corticosteroids, plasma exchange, and gamma globulin, comparable to the beneficial effects in the idiopathic variety of polymyositis. Corticosteroids in doses similar to those used in the treatment of idiopathic polymyositis are said to be effective in ameliorating the weakness but they entail special risks in immunocompromised patients.

The clinical and pathologic features of the ZVD-induced myopathy are much the same as those of HIV myopathy except that moderate pain is said to be characteristic of the drug-induced variety. The myopathy has been attributed to the mitochondrial toxicity of the drug, which may account for the presence of “ragged red” fibers in biopsy specimens. The onset of symptoms appears to be related to the sustained administration of high doses of the drug (1200 mg daily for a year or longer). Cessation or reduction in dosage of the drug diminishes the muscular discomfort within weeks, but strength recovers more slowly.

A myopathy due to human T-cell leukemia virus (HTLV-I) infection also simulates polymyositis in its clinical and histologic features. The illness occurs most often in endemic areas but is less common than the myelopathy that is associated with the virus (page 1059).

To be distinguished from the HIV- and ZVD-related inflammatory myopathies is the severe generalized muscle wasting that characterizes advanced AIDS. Muscle enzymes are normal and strength is little affected, considering the loss of muscle bulk. Histologically, there is atrophy of type 2 fibers. The pathogenesis of this cachectic syndrome is uncertain; it has been attributed to a multiplicity of systemic factors, including circulating catabolic cytokines.

Other Viral Myopathies

In most patients with pleurodynia (epidemic myalgia, Bornholm disease), muscle biopsies disclose no abnormalities and there is no clear explanation of the pain. However, group B Coxsackie virus has been isolated from striated muscle of patients with this disorder. Also, a necrotizing myositis has been suspected in a number of patients with influenza; under the electron microscope some muscle fibers have been reported to contain structures with the features of influenza virions. Malaise, myalgia, and slight weakness and stiffness were the clinical manifestations. Because of the myalgia, it is difficult to know how much of the weakness is only apparent. Recovery has been complete within a few weeks. In one patient with generalized myalgia and myoglobinuria, the influenza virus was isolated from muscle (Gamboa et al). These observations suggest that the intense muscle pain in certain viral illnesses might be due to a direct viral infection of muscle. However, there are many cases of influenza myalgia, mainly of the calves and thighs, such as those reported by Lundberg and by Antony and coworkers, in which it was not possible to establish that there was a muscular disorder at all. In the condition described as epidemic neuromyasthenia (benign myalgic encephalomyelitis, Icelandic disease)—in which influenza-like symptoms were combined with severe pain and weakness of muscles—a viral cause was postulated but an organism has never been isolated. The illness has been absorbed into the large and indistinct category of chronic fatigue syndrome (page 435).

Despite these ambiguities, viral myositis is an established entity in myopathology. Echo 9, adenovirus 21, herpes simplex, Epstein-Barr virus, and Mycoplasma pneumoniae have all been cited by Mastaglia and Ojeda and by others as causes of sporadic myositis with rhabdomyolysis in humans. In these infections the non-myopathic aspects of the disease usually predominate; in some of them, the evidence of invasion of muscle has not been fully substantiated since, in many instances, a nonspecific (Zenker-type) degeneration could have explained the muscle findings. The existence of a true postinfectious polymyositis is also unsettled.
IDIOPATHIC POLYMYOSITIS AND DERMATOMYOSITIS

These are relatively common diseases that affect primarily the striated muscle and skin and sometimes connective tissues as well. The term used reflects the tissues involved. If the inflammatory changes are restricted clinically to the striated muscles, the disease is called polymyositis (PM); if, in addition, the skin is involved, it is called dermatomyositis (DM), although the two diseases are now understood to be immunopathologically quite distinct. Either may be associated with a connective tissue disorder, in which case the designation called on is PM or DM with rheumatoid arthritis, rheumatic fever, lupus erythematosus, scleroderma, Sjögren syndrome, or mixed connective tissue disease, as the case may be. There is also an inconsistent relationship of these two diseases and systemic carcinoma, as discussed further on.

Both diseases have been known since the nineteenth century. Polymyositis was first described by Wagner in 1863 and 1887, and DM was established as an entity by Unverricht in a series of articles written from 1887 to 1891. A modern classification introduced in the monograph of Walton and Adams included categories associated with neoplasia and with connective tissue diseases. References to the original articles and a survey of the literature since that time can be found in the monograph of Kakulas and Adams and in the chapters on the PM and DM syndromes by Engel and colleagues.

It is mentioned here and emphasized further on that there is currently disagreement regarding the frequency of PM as an independent idiopathic entity. Amato and Griggs are of the opinion that most cases so classified are due to DM, inclusion body myopathy (IBM; also called inclusion body myositis), or related to a connective tissue disorder. The current authors are not in agreement with this point of view and continue to see well-studied and convincingly documented cases of classic PM.

Polymyositis

This is an idiopathic subacute or chronic and symmetrical weakness of proximal limb and trunk muscles without dermatitis. The onset is usually insidious and the course progressive over a period of several weeks or months. It may develop at almost any age and in either sex; however, a majority of patients are 30 to 60 years of age, and a smaller group shows a peak incidence at 15 years. Females predominate in all age groups. A febrile illness or benign infection may precede the weakness, but in most patients the first symptoms develop in the absence of these or other apparent initiating events.

The usual mode of onset is with a mainly painless weakness of the proximal limb muscles, especially of the hips and thighs and to a lesser extent the shoulder girdle and neck muscles. Often, the patient cannot easily determine the time of onset of weakness. Certain actions—such as arising from a deep chair or from a squatting or kneeling position, climbing or descending stairs, walking, putting an object on a high shelf, or combing the hair—become increasingly difficult. Pain of an aching variety in the buttocks, calves, or shoulders is experienced by only about 15 percent of patients and often indicates a combination of PM and rheumatoid arthritis, tendonitis, or other connective tissue disorder.

When the patient is first seen, many of the muscles of the trunk, shoulders, hips, upper arms, and thighs are usually involved. The posterior and anterior neck muscles (the head may loll) and the pharyngeal, striated esophageal, and laryngeal muscles (dysphagia and dysphonia) may be involved as well. In restricted forms of the disease, only the neck muscles or quadriceps may be implicated. Ocular muscles are not affected except in the rare (but well-described) instances of both PM and myasthenia gravis. The facial, tongue, and jaw muscles are only occasionally affected, and the distal muscles, namely the forearm, hand, leg, and foot are spared in 75 percent of cases. The respiratory muscles are weakened to a minor degree, and in an exceptional case there may be dyspnea, the cause of which is revealed only by an intercostal muscle biopsy (Thomas and Lancaster). Occasionally the early symptoms predominate in one proximal limb before becoming generalized.

The muscles are usually not tender, and atrophy and reduction in tendon reflexes, though sometimes present, are initially less pronounced than they are in patients with chronic denervation atrophy or with inclusion body myopathy (see further on). When reflexes are disproportionately reduced, one must think of an additional process such as systemic cancer with PM and polyneuritis, or IBM (see further on), Eaton-Lambert syndrome, or other more obscure forms of neuromyositis. As the weeks and months pass, the weakness and muscle atrophy progress unless treatment is initiated. Without physical therapy, fibrous contracture of muscles eventually develops. Some elderly individuals with a particularly chronic form of the disease may present with severe atrophy and fibrosis of muscles; the response to treatment in such cases is poor.

In both PM and DM, there may be involvement of organs other than muscle. In a surprising number of our cases of PM (and DM), cardiac abnormalities have been observed, and in a small proportion of these, unexpected sudden death has occurred. The cardiac manifestations have taken the form of relatively minor electrocardiographic changes, but several patients have had arrhythmias with clinical consequences. Among the fatal cases, about half have shown necrosis of myocardial fibers at autopsy, usually with only modest inflammatory changes. Interstitial lung disease is another known association in a few cases. Its frequency ranges from 5 to 47 percent in different series (see further on, under “Laboratory Findings in PM and DM”), but the lower figure is probably correct. Exceptionally, there is a low-grade fever, especially if joint pain coexists, but, as often, fever is due to unrecognized aspiration pneumonia.

Dermatomyositis

The presentation of muscle weakness is similar to that of polymyositis but the denominative feature is a rash. Most often, the skin changes precede the muscle syndrome and take the form of a localized or diffuse erythema, maculopapular eruption, scaling eczematoid dermatitis, or an exfoliative dermatitis. Sometimes, skin and muscle changes evolve together over a period of 2 or 3 weeks or less. A characteristic form of the skin lesions is patches of a scaly roughness over the extensor surfaces of joints (elbows, knuckles, and knees) with varying degrees of pink-purple coloration. Also highly typical is a lilac-colored (heliotrope) change in the skin over the eyelids, on the bridge of the nose, on the cheeks, and over the forehead; it may include a scaly component. Itching may be a troublesome symptom in regions of the other skin eruptions. This distribution suggests that the skin changes reflect heightened photosensitivity; a predominance of rash over the neck and upper shoulders has been termed the V sign, while rash over the shoulders and upper arms, the shawl sign. Periorbital and perioral edema are additional common findings but mainly in more fulminating cases. Red, raised papules may be present over exposed sur-
faces such as the elbows, knuckles, and distal and proximal interphalangeal joints (Gottron’s papules); these are particularly prominent in DM of childhood. Skin changes may be transient and in some instances are restricted to one or more patches of dermatitis. These sometimes evanescent and restricted skin manifestations are emphasized because they are frequently overlooked but provide the clues to distinguishing DM from PM. In the healing stage, the skin lesions leave whitened atrophic scars with a flat, scaly base.

In contrast to PM, DM affects children and adults about equally. Among adults, DM is more frequent in females whereas in childhood, males and females are affected equally.

Other signs of interest include periartricular and subcutaneous calcifications that are common in the childhood form. Signs of associated connective tissue disease are more frequent than in pure PM (see further on). The Raynaud phenomenon has been reported in nearly one-third of the patients and a similar number have dilated or thrombosed nailfold capillaries as commented later. Whether this signifies the presence of a concurrent connective tissue disease has never been clarified, but we consider that it does so. Others subsequently develop a mild form of scleroderma and an associated esophageal weakness may be demonstrated by fluoroscopy in up to 30 percent of all patients. The superior constrictors of the pharynx are then involved, but cinfluorography may be necessary to demonstrate the abnormality.

**Dermatomyositis of Childhood** Idiopathic PM occurs in children, but less frequently than it does in adults. Indeed, some of the myositis illnesses in children tend to be relatively benign but otherwise do not differ from those in adults. Far more frequently, however, there is a distinctive syndrome, described by Banker and Victor, which is also designated as dermatomyositis but differs in some respects from the usual adult form of the disease. In these children and adolescents there is a greater involvement of blood vessels in the connective tissue of multiple organs as well as in skin and muscle. As mentioned earlier, this childhood form of DM is equally distributed between the sexes. It begins, as a rule, with rather typical skin changes, accompanied by anorexia and fatigue. Erythematous discoloration of the upper eyelids (the previously described heliotrope rash), frequently occurring with edema, is another characteristic early sign. The erythema spreads to involve the periorbital regions, nose, malar areas, and upper lip as well as the skin over the knuckles, elbows, and knees. Cuticular overgrowth, subungual telangiectasia, and ulceration of the fingertips may be found. Capillary prominence in the nail beds and avascular regions in the cuticle are said to be characteristic (as mentioned earlier) and need to be sought with a magnifying lens or ophthalmoscope [these signs are also seen in the form of scleroderma termed CREST (caldinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia)].

Symptoms of weakness, stiffness, and pain in the muscles usually follow but may be concomitant with or rarely precede the skin manifestations. The muscular weakness is generalized but always more severe in the muscles of the shoulders and hips and proximal portions of the limbs. A ptotic gait, the result of fibrous contractures of flexors of the ankles, is a common later abnormality. Tendon reflexes are depressed or abolished, commensurate with the degree of muscle weakness. Intermittent low-grade fever, substernal and abdominal pain (like that of peptic ulcer), melena, and hematemesis from bowel infarction occur, the result of an accompanying systemic vasculitis.

The mode of progression of DM of childhood, like that of the adult form, is variable. In some cases, the weakness advances rapidly, involving all the muscles—including those of chewing, swallowing, talking, and breathing—and leading to total incapacitation. Perforation of the gastrointestinal tract from bowel infarction is often the immediate cause of death. In other patients there is slow progression or arrest of the disease process, and in a small number there may be a remission of muscle weakness. Flexion contractures at the elbows, hips, knees, and ankles and subcutaneous calcification and ulceration of the overlying skin, with extrusion of calcific debris, are common manifestations in the later stages of the disease.

**Connective Tissue Diseases with Polymyositis and Dermatomyositis** In both PM and DM, the inflammatory changes are often not confined to muscle but are associated with connective tissue diseases, such as rheumatoid arthritis, scleroderma, lupus erythematosus, or combinations thereof (mixed connective tissue disease); the same muscle changes are associated less often with the Sjögren syndrome (keratoconjunctivitis sicca, xerostomia). Conversely, in the aforementioned diseases, inflammatory muscle changes are frequently found, but in a small proportion of muscles and often asymptomatic. The incidence of these relationships cannot be stated with precision. A true necrotizing-inflammatory myopathy has been reported in up to 8 percent of cases of lupus erythematosus (higher than in our experience) and an even smaller proportion of cases of systemic sclerosis, rheumatoid arthritis, and Sjögren syndrome. The treatment of rheumatoid arthritis with D-penicillamine is believed to increase the incidence of, or perhaps independently precipitate, PM and DM.

Also notable is the sporadic co-occurrence of myositis with other putative autoimmune diseases such as myasthenia gravis and Hashimoto thyroiditis, and, less often, with a monoclonal paraprotein in the blood.

In the so-called overlap syndromes that incorporate connective tissue disease and myositis, there is usually greater muscular weakness and atrophy than can be accounted for by the muscle changes alone. Inasmuch as arthritis or periarticular inflammation may limit motion because of pain, result in disuse atrophy, and also at times cause a vasculitic mono- or polyneuritis, the interpretation of diminished strength in these autoimmune diseases is not easy. Malaise, aches, and pains are common and attributable mostly to the systemic disease. Sometimes the diagnosis must depend on muscle biopsy, EMG findings, and measurements of muscle enzymes in the serum as later described. In these complicated cases, the myositis may accompany the connective tissue disease or occur many years later.

It is worth commenting that PM may occur during pregnancy and that rarely the fetus is affected (most often the fetus and neonate are normal) with elevated CK levels for months postpartum (Mesina et al).

**Carcinoma with Polymyositis or Dermatomyositis** At one time this was a controversial subject and, in some respects, it remains so. The reported incidence of systemic malignancy with PM and DM has varied considerably from one series to another (see Engel et al and Buchbinder and Hill). In the large series of Sigurgeirsson et al, 9 percent of 396 patients with PM were found to have carcinoma, either at the time of diagnosis of the muscle disease or within 5 years of it. DeVere and Bradley reported that 29 percent of the overall group of DM patients had an associated carcinoma; this figure rose to 40 percent if the patient was over 40 years of age and to 66 percent if the patient was both male and over 40. This, however, is much higher than that reported in all other series,
including that from our own experience. The relationship between myositis and malignancy is not understood but nonetheless the connection appears valid, even if infrequent.

The neoplastic processes linked most often with myositis is lung and colon cancer in men and breast and ovarian cancer in women, however, tumors have been reported in nearly every organ of the body. In about half the cases, the PM or DM antedates the clinical manifestations of the malignancy, sometimes by 1 to 2 or more years, a duration that brings the association into question. The morbidity and mortality of patients with this combination is usually determined by the nature of the underlying tumor and its response to therapy. Occasionally, excision of the tumor is attended by remission of the myositis.

**Laboratory Findings in PM and DM** In the majority of patients with PM and DM, regardless of any clinical associations, serum levels of CK and other muscle enzymes such as aldolase, are elevated. Serum CK levels tend to be higher in PM than in DM because of the widespread single-fiber necrosis in the former (as described in the following section on pathologic changes). However, in DM, if there are infarcts in muscle or acute perifascicular degeneration, CK levels will be moderately elevated as well. The sedimentation rate may be normal or mildly elevated in both diseases.

It has been appreciated that many cases of PM and DM are associated with autoantibodies in the blood. Some of these are undoubtedly nonspecific markers of an autoimmune or inflammatory state but others may be of pathogenic significance. Tests for circulating rheumatoid factor or antinuclear antibody are positive in fewer than half of cases. A high titer of antinuclear antibody (ANA), in conjunction with elevated antiribonuclear antibodies, suggests the coexistence of systemic lupus or mixed connective tissue disease. It must be emphasized, however, that absent or low-titer ANA and a normal sedimentation rate do not exclude the diagnosis of PM—a fact that limits their diagnostic usefulness.

Of greater interest are the findings that almost one-half of patients with PM and DM in some series have antibodies against various cellular components of muscle, in particular, antibodies directed against cytoplasmic transfer ribonucleic acid (tRNA) synthetases (called anti-Jo1) or against the tRNA itself. These are fairly specific to PM and, to a lesser extent, to DM. The clinical disorders associated with these antibodies usually combine myositis and some combination of (1) interstitial lung disease, (2) arthritis, (3) Raynaud syndrome, and (4) thickening of the skin of the hands ("mechanic’s hands"). Following from the designation of the main type of antibody, these have been termed **synthetase syndromes**. Furthermore, an unexpectedly high proportion of cases of PM and DM show myositis-specific antibodies that are directed against a cytoplasmic ribonucleoprotein complex (the signal recognition particle, or SRP) or against a protein complex that is a nuclear helicase (Mi-2). The former is found in about 5 percent of cases of PM, DM, or IBM and in some series has carried a heightened risk of cardiac involvement. Other probably less specific antibodies are directed against constituents of a nucleolar protein complex (PM-Scl) and ribonucleoproteins (Ro/SS-A and La/SS-B). In our view, these various autoantibodies, with the possible exception of anti-Jo1, are not especially useful as primary diagnostic tools but they have a role in refining diagnosis. For example, a positive Jo-1 antibody precludes the diagnosis of inclusion body myopathy. As discussed later, the presence of these antibodies also underscores the role for the humoral immune system in the pathogenesis of PM and raises opportunities for investigation.

Myoglobinuria can be detected in the majority of patients with an acute necrotizing form of the disease provided that a sensitive immunoassay procedure is used.

The EMG is quite helpful in diagnosis but has been normal in about 10 percent of our cases even when many muscles are sampled. It discloses a typical “myopathic pattern,” i.e., many abnormally brief action potentials of low voltage, in addition to numerous fibrillation potentials, trains of positive sharp waves, occasional polyphasic units, and myotonicty activity—all but the brief potentials actually reflecting minor degrees of denervation from damage to the terminal axons (see Chap. 45). These findings are most apparent in weak muscles and are almost always seen when proximal weakness is well developed, but they may be observed in clinically unaffected areas as well. Indolent and chronic cases in which fibrosis of muscle and wasting have supervened may show polyphasic units that simulate denervation-reinnervation changes, alongside myopathic motor units. The EMG is also helpful in choosing a muscle for biopsy sampling but care must be taken not to obtain tissue from precisely the same site as a recent EMG needle insertion.

As stated earlier, the electrocardiogram has been abnormal in many of our cases and this finding may suggest the need for vigilance regarding cardiac symptoms and arrhythmias.

The muscle biopsy, if taken from an affected muscle, usually demonstrates the typical pathologic changes, with the limitations described below. It remains the essential diagnostic test. MRI may also be helpful in the assessment of myositis. Abnormalities in T1 and T2 signal intensity define regions of increased water content and inflammation in muscle, and spectroscopic studies demonstrate regional deficits in energy production. While MRI techniques cannot at this time replace a biopsy for diagnosis, they can define the distribution of lesion and thereby aid in targeting the muscle biopsy as well as provide a useful index the efficacy of drug therapy and, in some cases, distinguish IBM from either PM or metabolic muscle disease (see Lodi et al and also Dion et al).

**Pathologic Changes in PM and DM** Because of the scattered distribution of inflammatory lesions, and destructive changes, only part (or none) of the complex of pathologic changes may be divulged in any one biopsy specimen. Because of this limitation, more than one site of biopsy is advisable in some cases.

The principal changes in idiopathic PM consist of widespread destruction of segments of muscle fibers with an inflammatory reaction, i.e., phagocytosis of muscle fibers by mononuclear cells and infiltration with a varying number of lymphocytes and lesser numbers of other mononuclear and plasma cells. Evidence of regenerative activity of muscle, mainly in the form of proliferating sarcoclemmal nuclei, basophilic (RNA-rich) sarcomplasm, and new myofibrils, is evident in damaged regions. Many of the residual muscle fibers are small, with increased numbers of sarcoclemmal nuclei. Some of the small fibers are found in clusters, the result of splitting of regenerating fibers. Either the degeneration of muscle fibers or an infiltration of inflammatory cells may predominate in any given biopsy specimen, though both types of change are in evidence at autopsy.

In a single section from a biopsy sample, there may be only necrosis and phagocytosis of individual muscle fibers without infiltrates of inflammatory cells, or the reverse may be observed. However, in serial sections, muscle necrosis is always shown to be near inflammatory infiltrates. Repeated attacks of a necrotizing myositis appear to exhaust the regenerative potential of the muscles,
so that fiber loss, fibrosis, and residual thin and large fibers in haphazard arrangement may eventually impart a dystrophic aspect to the lesions. For all these reasons the pathologic picture can be correctly interpreted only in relation to the clinical and other laboratory data. Guidelines for the interpretation of the muscle biopsy reflecting these comments, a critical step in correct diagnosis of the inflammatory myopathies, are given in the review by Dalakas and Hohlfeld.

In DM, there are several additional and distinctive histopathologic changes. In contrast to the evident necrosis of single-fibers of PM, DM is characterized instead by perifascicular muscle fiber atrophy (referring to changes at the periphery of a fascicle, for reasons noted below). Moreover, the inflammatory infiltrates in DM predominate in the perimysial connective tissue, whereas in PM they are scattered throughout the muscle and are most prominent in relation to the muscle fiber membrane and the endomysium. The muscle lesions in dermatomyositis of childhood are similar to those of the adult form, only greatly accentuated. In a biopsy sample, the diagnosis can be inferred from the perifascicular degeneration and atrophy of muscle fibers.

Even more distinctive in DM are changes of a vasculitic nature in the small intramuscular blood vessels. Endothelial alterations (tubular aggregates in the endothelial cytoplasm) and occlusion of vessels by fibrin thrombi are the main abnormalities. Occlusion of small vessels also involves the intrafascicular nerves, so that the affected muscle may show both zones of infarction and denervation atrophy. The same vascular changes underlie the lesions in the connective tissue of skin, subcutaneous tissue, and gastrointestinal tract. This small vessel vasculitis is not seen in PM. The perifascicular muscle fiber atrophy is probably a result of an ischemic process set up by capillary occlusion.

**Etiology and Pathogenesis**

The cause of idiopathic PM and DM, as the term indicates, is unknown. All attempts to isolate an infective agent have been unsuccessful. Several electron microscopists have observed virus-like particles in muscle fibers, but their causative role has not been proved. A polymyositis illness has not been induced in animals by injections of affected muscle. Nevertheless, the notion that an autoimmune mechanism is operative in PM and DM is supported by the association of these disorders with a number of the more clearly established autoimmune diseases (myasthenia gravis, Hashimoto thyroiditis, scleroderma, Sjögren disease, rheumatoid arthritis, Waldenstrom macroglobulinemia, agammaglobulinemia, and the other connective tissue diseases mentioned earlier). Further evidence of an autoimmune nature is the presence of specific autoantibodies in nearly half of cases as described earlier.

Immunopathologic studies have partially substantiated an autoimmune mechanisms and suggested, in addition, that PM and DM can be distinguished from one another on the basis of their immunopathologic characteristics. In DM, immune complexes, IgG, IgM, complement (C3), and membrane-attack complexes are deposited in the walls of venules and arterioles, indicating that the immune response is directed primarily against intramuscular blood vessels (Whitaker and Engel; Kissel et al). Such a response is entirely lacking in PM (and in IBM, discussed further on). Engel and Arahata have demonstrated a difference between the two disorders on the basis of the subsets and locations of lymphocytes that make up the intramuscular inflammatory aggregates. In PM, there are a large number of activated T cells, mainly of the CD8 class, whereas B cells are sparse. Moreover, T cells, accompanied by macrophages enclose and invade nonnecrotic muscle fibers. In DM, very few fibers are affected in this manner, and the percentage of B cells at all sites is significantly higher than it is in PM. Engel and Arahata interpreted these differences as indicating that the effector response in DM is predominantly humoral, whereas in PM the response is composed of cytotoxic T cells, clones of which have been sensitized to a yet undefined surface antigen on the muscle fiber.

**Diagnosis**

This is secure if there is a subacutely evolving proximal weakness, typical changes in the muscle biopsy, EMG abnormalities of myopathic type with scattered fibrillation potentials, and elevated serum levels of CK. For DM, the finding of one of the typical dermatologic features is of great value. However, all these criteria have been satisfied in only half of our cases, even in those who are later shown to be responsive to corticosteroids (see later). One must, therefore, often accept the diagnosis when most of the criteria are met. Fever, pain beyond that attributable to arthritic involvement, or a greatly elevated sedimentation rate (> 100 mm/h) suggest an alternative diagnosis. The distinction from IBM, discussed further on, can be difficult and depends to a large degree on the muscle biopsy. As mentioned earlier, there has been considerable discussion regarding the diagnostic criteria for the inflammatory myopathies; some of these issues and reservations about the frequency with which the diagnosis is made are articulated by Amato and Griggs. The main point of controversy has been the proposal that true PM is rare and greatly overdiagnosed (see van der Muelen et al), a notion with which we do not fully agree. In contrast, inflammatory myopathy coexists with numerous systemic diseases as discussed, and some authors consider it to be a syndrome rather than a disease.

The problem of determining which patients should have an extensive evaluation for a systemic malignancy and for connective tissue disease is a difficult one. Opinions vary on this point but we have adopted the practice of careful inspection of the chest x-ray on all patients and of undertaking a more extensive evaluation in patients over age 55 or in smokers of any age. The evaluation in the latter group includes chest and abdominal computed tomography scans, stool guaiac CA-125, CEA, etc. In patients with recent weight loss, anorexia, or other symptoms suggestive of malignancy we have included upper and lower endoscopy and even occasionally resorted to a body positron emission tomography scan.

The anti-Jo1 antibody test can be obtained in patients with interstitial lung disease or rheumatoid arthritis (it is not referable to an underlying cancer). A routine evaluation for the conventional connective tissue diseases is only necessary if there is clinical evidence to support such a diagnosis.

In addition to these issues we call attention to the following problems that have arisen repeatedly in connection with the diagnosis of PM:

1. The patient with proximal muscle weakness incorrectly diagnosed as having progressive muscular dystrophy. Points in favor of PM are: (a) lack of family history; (b) older age at onset; (c) more rapid evolution of weakness; (d) evidence, past or present, of other connective tissue diseases; (e) high serum CK and aldolase values; (f) many fibrillation potentials on EMG; (g) marked degeneration and regeneration in muscle biopsy; and finally, if there is still doubt, (h) unmistakable improvement with corticosteroid therapy.

2. The patient with a connective tissue disease (rheumatoid arthritis, scleroderma, lupus erythematosus, Sjögren syndrome) suspected of having PM in addition. Pain in these conditions...
The patient with restricted muscle weakness

3. When muscle pain is a prominent feature, polymyalgia rheumatica must be differentiated. This syndrome is characterized by pain, stiffness, and tenderness in the muscles of the neck, shoulders, and arms and sometimes of the hips and thighs; even passive motion of the limbs causes pain because of the periarticular locus of this disease. A high sedimentation rate, usually above 65 mm/h, is a diagnostic feature but more typically the value is close to 100 mm/h, levels higher than they are in myositis. Biopsy of the temporal artery frequently discloses a giant-cell arteritis. CK levels—and of course muscle biopsy—are normal. Rapid disappearance of pain with administration of small doses of prednisone is also diagnostic of polymyalgia rheumatica (see page 1281).

4. The patient with restricted muscle weakness. Weakness or paralysis of the posterior neck muscles, with inability to hold up the head, restricted bilateral quadriceps weakness, and other limited pelvicurals palsies are examples. Most often, the head-hanging or head-lolling syndrome proves to be due to PM and the other syndromes to restricted forms of dystrophy or to motor neuron disease. Inclusion body myositis is the main alternative consideration in cases of neck or quadriceps weakness, particularly if the latter weakness is asymmetric; muscle enzymes in the serum are normal or slightly elevated. Electromyography and biopsy are helpful in diagnosis.

5. The patient with diffuse myalgia and fatigability. Most such patients with diffuse myalgia and fatigability have proved to be neurasthenic or depressed and rarely myopathic. A few cases will be found to be due to a toxic myopathy, particularly from one of the statin class of drugs. Hypothyroidism, McArthur disease, hyperparathyroidism, steroid myopathy, adrenal insufficiency, hyperinsulinemia, and early rheumatoid arthritis must be ruled out by appropriate studies (these toxic and metabolic myopathies are discussed in Chap. 51). Features that virtually exclude a PM are (a) lack of reduced peak power of contraction and (b) normal EMG, serum enzymes, and muscle biopsy.

6. The muscle biopsy of the patient with a clinical picture of PM discloses a noncaseating granulomatous reaction consistent with sarcoid (see further on).

Treatment

Most clinicians agree that corticosteroids (prednisone, 1 mg/kg, as a single daily dose orally, or intravenously) are the first line of therapy for both PM and DM. The response to corticosteroids is monitored by careful testing of strength and measurement of CK (not by following the ESR). In patients who respond, the serum CK decreases before the weakness subsides; with relapse, the serum CK rises before weakness returns. Once recovery has begun, typically several weeks or longer, and the dosage may be reduced gradually toward 20 mg daily. It is then appropriate to attempt to control the disease with an alternate-day schedule with double this amount (i.e., prednisone, 40 mg every other day) in order to reduce the side effects of the drug. After cautious reduction of prednisone over a period of 6 months to a year or longer, the patient can usually be maintained on doses of 7.5 to 20 mg daily, with the aim of eventual discontinuation of the drug. Corticosteroids should not be discontinued prematurely, for the relapse that may follow is often more difficult to treat than the original illness.

In acute and particularly severe cases, treatment may be facilitated by the use initially of high-dose “pulse” methylprednisolone (1 g infused over 2 h each day for 3 to 5 days). This form of treatment should be regarded as a temporary measure until oral prednisone becomes effective. Alternatively, or sometimes in tandem with this approach, intravenous immunoglobulin or plasma exchanges may be instituted. In patients with DM who respond poorly to corticosteroids and other immunosuppressants or are severely affected early on, the addition of intravenous immunoglobulin (IVIG) infusions often proves helpful—although several courses of treatment at monthly intervals may be required to achieve sustained improvement. In several controlled studies of small numbers of patients with DM, practically all showed improvement in muscle strength and in skin changes and a reduction in CK concentration, (see Dalakas; Mastaglia et al). PM has also been reported to respond favorably to treatment with IVIG, but the evidence is less firm. Further controlled studies are required to corroborate these reports and to establish, in both PM and DM, the optimal doses and modes of administration. It is noteworthy from our experience that IVIG has seldom been effective in PM or DM when used alone or as initial therapy.

Some patients who cannot tolerate, or are refractory to, prednisone may also respond favorably to oral azathioprine (150 to 300 mg/day), with care being taken to keep the white blood cell (WBC) level below about 3000 cells per cubic millimeter. Currently favored as an adjunct to steroids is methotrexate (5 to 10 mg/week in three divided oral doses, increased by 2.5 mg per week, to a total dose of 20 mg weekly). Methotrexate or azathioprine should generally be given along with the smallest effective doses (15 to 25 mg) of prednisone. Some clinicians favor, from the beginning, a combination of prednisone in low dosage and one of these immunosuppressant drugs, and this approach is generally necessary when systemic vasculitis or interstitial pneumonia is coupled with DM. The steroid-sparing effects of azathioprine may also be useful in patients requiring long-term therapy, Cyclophosphamide, which is a useful drug in the treatment of Wegener granulomatosis, polyarteritis, and perhaps other vasculitides, is said to be of lesser value in PM, but several of our rheumatologist colleagues recommend it and we have seen good responses in adults. Mycophenolate mofetil has also been introduced and has allowed a reduction in steroid dose within several months in both PM and DM, according to a number of anecdotal reports. Cyclosporine has also been used in recalcitrant cases; it has few advantages over other immunosuppressant drugs and has a number of potentially serious side effects, including nephrotoxicity. Whole-body radiation is said to be helpful in a few drug-resistant cases, but the side effects should be considered.

Prognosis

Except for patients with malignancy, the prognosis in adult PM and DM is favorable. Only a small proportion of patients with PM succumb to the disease, and then usually from a secondary pulmonary complication or from myocarditis as already mentioned. Several of our patients have had severe aspiration pneumonias as a result of their dysphagia. The period of activity of disease varies considerably but is usually around 2 years in both the child and adult. As indicated earlier, the majority improve with corticosteroid therapy, but many are left with varying degrees of weakness of the
shoulders and hips. Approximately 20 percent of our patients have recovered completely after association of steroid therapy, and long-term remissions have been achieved in about an equal number. The extent of recovery is roughly proportional to the acuteness and severity of the disease and the duration of symptoms prior to institution of therapy. Patients with acute or subacute PM in whom treatment is begun soon after the onset of symptoms have the best prognosis. In the series of Devere and Bradley, in which patients were treated early, there was remission in over 50 percent of cases, whereas in the series of Riddoch and Morgan-Hughes, in which patients were treated more than 2 years after onset of the disease, the rate was considerably lower. These patients who have come to our attention after a long period of proximal weakness and with substantial muscle atrophy have not recovered well, although some improvement can be expected over years.

Even in patients with a coexistent malignancy, muscle weakness may lessen and serum enzyme levels decline in response to corticosteroid therapy, but weakness returns after a few months and may then be resistant to further treatment. As already stated, if the tumor is successfully removed, the muscle symptoms may remit but even this experience has not been uniform.

The overall mortality after several years ranges around 15 percent, being higher in childhood DM, in PM with connective tissue diseases, and, of course, with malignancy.

**INCLUSION BODY MYOPATHY**

Inclusion body myositis, or myopathy, is the third major form of idiopathic inflammatory myopathy and, depending on the care taken with histologic diagnosis, is found to be as common as PM and DM. Its defining features, the intracytoplasmic and intranuclear inclusions, were first described in 1965 by Adams and colleagues, who also drew attention to a number of clinical attributes now considered characteristic. By 1994, more than 240 sporadic cases and 59 familial ones had been recorded in the medical literature (Mikol and Engel), but the diagnosis is now made so frequently that this low number almost certainly reflects the misidentification of IBM as PM in the past. Garlepp and Mastaglia concluded that over one-third of cases of inflammatory myopathy, especially in men, are of this type. A set of clinical and pathologic diagnostic criteria for the disease has been proposed by Griggs and coworkers and are useful for research purposes.

The disease predominates in males (in a ratio of 3:1) and has its onset in middle or late adult life. Practically all instances occur sporadically but an unrelated inherited form, either autosomal recessive or dominant, is well known (Cole et al, Neville et al). Many, but not all of these forms of autosomal recessive IBM are caused by a mutation on chromosome 9p1-q1 (Argov et al, Eisenberg et al). An autosomal recessive distal myopathy with rimmed vacuoles (a central feature of IBM; see later) has also been described in Japan. The process has been shown to be allelic to the same 9p chromosomal abnormality which in turn gives rise to most cases of hereditary IBM. The mutation involves an unusual bifunctional protein that is both a kinase and an epimerase, defects of which reduce the number of sugar and sialic acid residues on muscle proteins. These chemical changes increase the susceptibility of the muscle membrane to injury, similar in a general way to the circumstances in the muscular dystrophies. One must express some skepticism about the validity of linking sporadic and familial cases on the basis of a single histopathologic finding (the inclusions).

Diabetes, any one of a variety of autoimmune diseases, and a relatively mild polyneuropathy are associated in about 20 percent of the sporadic cases of IBM, but an association with malignancy or connective tissue disease has not been established.

**Clinical Manifestations** The illness is characterized by a steadily progressive, painless muscular weakness and atrophy, which may be generalized or affect the limbs selectively and often asymmetrically. Either the proximal or distal muscles may be affected, or the limbs may be involved more or less evenly. In about 20 percent of cases the disease begins with focal weakness of the quadriceps, finger or wrist flexors, or lower leg muscles on one or both sides and spreads to other muscle groups only after many months or years. Selective weakness of the flexor pollicis longus is a particularly characteristic pattern of involvement, and isolated quadriceps weakness or neck extensor weakness are other patterns that should bring the diagnosis to mind. The tendon reflexes are normal initially but diminish in about half the patients as the disease progresses. Interestingly, the knee jerks may be depressed or lost even without much in the way of quadriceps weakness; the opposite is true in PM, i.e., as a rule, the reflexes are spared until the quadriceps is extremely weak. Dysphagia is common (Wintzen et al), and some type of cardiovascular abnormality has been seen in a few cases but not with the frequency of changes in PM. The selective or asymmetric involvement of distal muscles may suggest the erroneous diagnosis of motor neuron disease.

The muscle weakness in familial IBM begins in early childhood and usually spares the quadriceps. Also, in the familial form, unlike in sporadic cases, the muscles lack inflammatory changes—for which reason the designation familial IBM is more appropriate.

**Laboratory and Muscle Biopsy Features** The CK is normal or slightly elevated, generally showing lower levels than in cases of PM with comparable amounts of weakness. EMG abnormalities are much like those found in PM as discussed earlier. In addition, a small proportion of IBM patients display a more frankly neuropathic EMG pattern, mainly with very numerous fibrillation potentials, particularly in the distal limb muscles.

The diagnosis ultimately depends on virtually diagnostic features in the muscle biopsy. There are structural abnormalities of muscle fibers and inflammatory changes. The latter are identical to but usually of lesser severity than those observed in idiopathic PM. (The infiltrating cells are mainly T cells of the CD8 type.) However, the derminative finding is of intracytoplasmic subsarcolemmal vacuoles and eosinophilic inclusions in both the cytoplasm and nuclei of degenerating muscle fibers. The vacuoles contain, and are rimmed by, basophilic granular material (“rimmed vacuoles”), a point of departure from the vacuoles seen inconsistently in PM. Special stains, notably Gomori trichrome, and extensive inspection of biopsy specimens are required to disclose these inclusions, for they are infrequent, widely dispersed, and easily overlooked. The inclusions are also congophilic, i.e., they stain positively for β-amyloid protein, the detection of which is enhanced by the use of fluorescence illumination (Askanas et al). As noted in subsequent chapters, similar inclusions are found in a number of other muscle diseases and are not in and of themselves diagnostic, especially without the destructive and mildly inflammatory changes. Also, the clinical context in which these other diseases occur usually cause little difficulty in identifying the inclusions as an ancillary and minor abnormality.

Ultrastructural studies show that the protein inclusion accumulates at or near foci of abnormal tubulofilamentous structures in
both the nuclei and cytoplasm. The nature of these diverse changes is obscure. The tubulofilamentous inclusions have suggested a viral origin, but one has never been isolated and serologic studies have failed to substantiate a viral causation except perhaps for one patient in whom adenovirus type 2 was isolated from a biopsy specimen (Mikol and Engel). No evidence has emerged to date to suggest an autoimmune mechanism, and the inflammatory component, although similar to PM, is thought to be possibly a secondary phenomenon as noted later.

**Treatment** Inclusion body myositis has not responded in any consistent fashion to treatment with corticosteroids or other immunosuppressive drugs. Indeed, the disease should be suspected in recalcitrant cases of apparent PM. Despite this, because a few patients improve slightly or cease worsening with steroids, a severalfourth trial is often recommended (Lotz et al). The level of CK and the degree of leukocyte infiltration of muscle often diminish with corticosteroid treatment despite a lack of clinical improvement. On this basis, Barohn and coworkers have suggested, as alluded to earlier, that the inflammatory response is not a primary cause of muscle destruction. Sayres and colleagues concluded in a review of 32 patients that low-dose methotrexate and corticosteroids may slow the progression of disease, but this regimen has not been widely adopted. In a few cases there has been brief improvement in response to IVIG, especially in the weakened muscles involved in swallowing, but the gains have been unsupported and serial histopathologic examinations have detected no change. Plasma exchange and leukocytapheresis have been tried, also with generally discouraging results. The disease in most patients is relentlessly progressive over many years, sometimes very slowly, and no method of treatment has altered the long-term prognosis. Sometimes, the process remains fairly restricted for up to a decade, thereby creating less disability than in cases that generalize.

**OTHER INFLAMMATORY MYOPATHIES**

Included under this heading are a large number of unrelated myositis and certain rare forms of focal myositis and relatively minor changes in muscle that occur in the course of inflammatory diseases of blood vessels or disseminated or systemic infections or curiously, with thymoma. Most of them do not warrant extensive consideration here but are described in detail in monographs devoted to muscle disease (see Banker). We are uncertain how to place the newly described and undoubted rare entity of myositis with abundant macrophage infiltration and aluminum hydroxide crystalline deposits. A type of fasciitis that is also characterized by pronounced infiltration of macrophages has been related to vaccinations that contain the aluminum compound, but the myositis is not related to this aforementioned entity (see Bassez et al).

Three inflammatory myopathic diseases, however, are quite distinctive and of interest to neurologists: (1) the eosinophilic myositis, fasciitis and myalgia syndrome, (2) orbital myositis, and (3) sarcoidosis of muscle.

**Eosinophilic Myositis and Fasciitis** This term has been applied to four separate and probably overlapping clinical entities: (1) eosinophilic fasciitis, (2) eosinophilic monomyositis (sometimes multiplex), (3) eosinophilic PM, and (4) the eosinophilia-myalgia syndrome.

**Eosinophilic Fasciitis** This condition, mistaken for PM, was originally reported by Shulman in 1974. He described two men with a scleroderma-like appearance of the skin and flexion contractions at the knees and elbows associated with hyperglobulinemia, elevated sedimentation rate, and eosinophilia. Biopsy revealed greatly thickened fascia, extending from the subcutaneous tissue to the muscle and infiltrated with plasma cells, lymphocytes, and many eosinophils; the muscle itself appeared normal and the skin lacked the characteristic histologic changes of scleroderma. One of Shulman’s patients recovered in response to prednisone.

The many reports that followed have fully substantiated and amplified Shulman’s original description. The disease predominates in men, in a ratio of 2:1. Symptoms appear between the ages of 30 and 60 years in most cases and are often precipitated by heavy exercise (Michet et al). Initially there may be low-grade fever and myalgia, followed by the subacute development of diffuse cutaneous thickening and limitation of movement of small and large joints. In some patients, proximal muscle weakness and eosinophilic infiltration of muscle can be demonstrated (Michet et al). Repeated examinations of the blood disclose an eosinophilia in most but not all patients.

Usually, the disease remits spontaneously or responds well to corticosteroids. A small number relapse and do not respond to treatment, and some have developed aplastic anemia and a form of lympho- or myeloproliferative disease.

**Eosinophilic Monomyositis** Painful swelling of a calf muscle or, less frequently, some other muscle has been the chief characteristic of this disorder. A painful mass forms within the muscle. Biopsy discloses inflammatory necrosis and edema of the interstitial tissues; the infiltrates contain variable numbers of eosinophils. This disorder is typified by one of our patients—a young woman who developed such an inflammatory mass first in one calf and then, 3 months later, in the other. The response to prednisone in this patient was dramatic; the swelling and pain subsided in 2 to 3 weeks, and power of contraction was then found to be normal. When the connective tissue and muscle are both damaged, a chaotic regeneration of fibroblasts and myoblasts may occur, forming a pseudotumor mass that may persist indefinitely.

**Eosinophilic Polymyositis** Layzer and associates described a third form of eosinophilic disorder, which they classified as a true subacute PM. Their patients were adults in whom predominantly proximal weakness evolved over several weeks. The other features of the muscle disorder were also typical of PM except that the inflammatory infiltration was predominantly eosinophilic and the muscles were swollen and painful. Moreover, in each case the muscle disorder was part of a severe and widespread systemic illness typical of the hypereosinophilic syndrome. The systemic manifestations included a striking eosinophilia of the blood (20 to 55 percent of the white blood cells), cardiac involvement (conduction disturbances and congestive failure), vascular disorder (Raynaud phenomenon, subungual hemorrhages), pulmonary infiltrates, strokes, anemia, neuropathy, and hypergammaglobulinemia. There was a favorable response to corticosteroids in two patients, but in a third the outcome was fatal within 9 months. Layzer and coworkers noted that a lack of necrotizing arteritis distinguished this process from polyarteritis nodosa and Churg-Strauss disease. No infective agent could be isolated. An allergic mechanism seems a likely cause of the lesions, and in the present authors’ view one cannot exclude an angitis as a cause of all of the lesions.

The last two of these previously mentioned syndromes (eosinophilic monomyositis and PM) have overlapping features, as shown by Stark’s cases, in which a monomyositis was accompanied by several of the systemic features described by Layzer et al.
**Eosinophilia-Myalgia Syndrome** Beginning in 1980, a number of sporadic reports documented a lingering systemic illness characterized by severe generalized myalgia and eosinophilia of the peripheral blood following the ingestion of L-tryptophan. In late 1989 and early 1990, there occurred a massive outbreak of this eosinophilia-myalgia syndrome, as the illness came to be called. Over 1200 cases were reported to the Centers for Disease Control (Medsger), and we examined several of them. The outbreak was ultimately traced to the use of nonprescription L-tryptophan tablets supplied by a single manufacturer and contaminated by a dityrptophan-aminol of acetaldehyde (Mayeno et al).

The onset was relatively acute, with fatigue, low-grade fever, and eosinophilia (>1000 cells per cubic millimeter). Muscle pain and tenderness, cramps, weakness, paresthesias of the extremities, and induration of the skin were the main clinical features. A severe axonal neuropathy with slow and incomplete recovery was associated in some cases. Biopsies of the skin fascia, muscle, and peripheral nerve disclosed a microangiopathy and an inflammatory reaction in connective tissue structures—changes like those observed in scleroderma, eosinophilic fasciitis, and the toxic oil syndrome. The latter syndrome, caused by the ingestion of contaminated rapeseed oil (in Spain, 1981), gave rise to a constellation of symptoms like those observed in L-tryptophan myalgia.

A severe axonal neuropathy characterized by severe generalized myalgia and eosinophilia of the peripheral blood following the ingestion of L-tryptophan. In late 1989 and early 1990, there occurred a massive outbreak of this illness, as the illness came to be called. Over 1200 cases were reported to the Centers for Disease Control (Medsger), and we examined several of them. Biopsies of the skin fascia, muscle, and peripheral nerve disclosed a microangiopathy and an inflammatory reaction in connective tissue structures—changes like those observed in scleroderma, eosinophilic fasciitis, and the toxic oil syndrome. The latter syndrome, caused by the ingestion of contaminated rapeseed oil (in Spain, 1981), gave rise to a constellation of symptoms like those observed in L-tryptophan myalgia.

**Acute Orbital Myositis** Among the many cases of orbital inflammatory disease (pseudotumor of the orbit, page 234), there is a small group in whom the inflammatory process appears to be localized to the extraocular muscles. To this latter group the term *acute orbital myositis* has been applied. The abrupt onset of orbital pain that is made worse by eye motion, redness of the conjunctiva adjacent to the muscle insertions, diplopia caused by restrictions of ocular movements, lid edema, and mild proptosis are the main clinical features. It may spread from one orbit to the other. The erythrocyte sedimentation rate is usually elevated and the patient may feel generally unwell, but only rarely can the ocular disorder be related to a connective tissue disease or any other specific systemic disease. Computed tomography and MRI have proved to be particularly useful in demonstrating the swollen ocular muscles or muscle and separating orbital myositis from the many other remitting inflammatory orbital and retro-orbital conditions (Dua et al.). As a rule, acute orbital myositis resolves spontaneously in a matter of a few weeks or a month or two, although it may recur in the same or the opposite eye. Administration of steroids appears to hasten recovery.

**Sarcoid Myopathy, Granulomatous Myositis, and Localized Nodular Myositis**

Although there are undoubted examples of muscle involvement in patients with sarcoidosis, they seem to be less frequent and less certain than would appear from the medical literature. In some cases, sarcoid myopathy becomes evident as a slowly progressive, occasionally fulminant, painless proximal weakness. The CK and angiotensin-converting enzyme levels are elevated. Muscle biopsy discloses the presence of numerous noncaseating granulomas. It is important to note that such lesions may also be found in patients with sarcoidosis who have no weakness. Treatment with moderate doses of corticosteroids (prednisone, 25 to 50 mg daily) is usually effective in symptomatic cases, but an immunosuppressive agent such as cyclosporine may have to be given in addition if improvement is not evident in several weeks.

Much more puzzling have been cases of myopathy with the clinical features of idiopathic PM and the presence of noncaseating granulomas in the muscle biopsy but with no evidence of sarcoidosis of the nervous system, lungs, bone, skin, or lymph nodes. Such cases call into question the validity of a muscle granuloma as a criterion of sarcoidosis, but the matter cannot be settled until we have better laboratory tests than are now available. These cases are presently classified as *granulomatous myositis* and, if limited to one or a small group of muscles, *localized nodular myositis* (Cumming et al.). We suspect that such lesions have several clinical associations. In one syndrome, described by Namba and colleagues, this type of myositis was combined with myasthenia gravis, myocardiitis, and thyroiditis. The process has, on a few occasions, been associated with Crohn disease. Electron microscopy in some instances has disclosed muscle fiber invasion by lymphocytes, suggesting a cell-mediated immune reaction. Very rarely, a granulomatous myositis may complicate tuberculosis or syphilis.

CHAPTER 50
THE MUSCULAR DYSTROPHIES

The muscular dystrophies are a group of progressive hereditary degenerative diseases of skeletal muscles. The innervation of the affected muscles, in contrast to that of the neuropathic and spinal atrophies, is unaffected. Indeed, confirmation that these disorders originated in muscle came from the demonstration of intact spinal motor neurons, muscular nerves, and nerve endings in the presence of severe degenerative changes in the muscle fibers. In the last several decades final proof of this concept has come from the observations that genetic defects in the muscular dystrophies often involve genes that are expressed only in muscle. The symmetrical distribution of muscular weakness and atrophy, intact sensations, preservation of cutaneous reflexes, and a strong heredofamilial incidence are the characteristic features of this group and serve to set them apart on clinical grounds alone. The intensity of the degenerative changes in muscle and the cellular response and the vigor of the regenerative changes distinguish the dystrophies histologically and also have implications regarding their pathogenesis. The term dystrophy should, therefore, be reserved for the purely degenerative muscular disease of hereditary type and all other progressive diseases of muscle should be referred to as myopathies or polymyopathies. The latter category of more benign and relatively nonprogressive myopathies—each named largely on its special histopathologic appearance such as central core, nemaline, mitochondrial, and centronuclear diseases—present a greater difficulty in classification. Like the dystrophies, they are primarily diseases of muscle and are heredofamilial in nature; but they are placed in a separate category because of nonprogressive or slowly progressive course and their distinctive histochemistry and ultrastructure (Chap. 52).

The current clinical classification of the muscular dystrophies is based mainly on the distribution of the dominant muscle weakness, however, several of the classical types have retained their eponymic designations; hence: Duchenne-Becker, Emery-Dreifuss, and facioscapulohumeral, limb-girdle, oculopharyngeal, and distal types. To these are added myotonic dystrophy and a group of so-called congenital muscular dystrophies, usually severe in degree. The extraordinary depth of information regarding the molecular nature of the dystrophies is one of the most gratifying developments of modern neuroscience. The majority of the dystrophies are due to changes in structural elements of the muscle cell, mainly in its membrane, but other important categories are being identified, such as mutated messenger RNA. In keeping with the outlook expressed throughout the book, we adhere to a clinical orientation in describing the muscular dystrophies but make clear the idea that treatment in the future will be dominated by understanding of molecular mechanisms. A modern classification still separates the muscular dystrophies according to the traditional clinical types and their patterns of mendelian inheritance but also incorporates the nature and locus of the abnormal gene and the defective gene product. Each of the muscular dystrophies is subsequently described in accordance with this scheme.

Historical Background The differentiation of dystrophic diseases of muscle from those secondary to neuronal degeneration was an achievement of neurologists of the second half of the nineteenth century. Isolated cases of muscular dystrophy had been described earlier, but no distinction was made between neuropathic and myopathic disease. Thus, Little had described what appears to be Duchenne muscular dystrophy in lectures given at the Royal Orthopedic Hospital in 1843 and 1844. Meryon in 1852 gave the first clear description of progressive weakness and atrophy of muscle in young boys who, at autopsy, had an intact spinal cord and nerves—a fact that led him to postulate an “idiopathic disease of muscles, dependent perhaps on defective nutrition.” In 1855, the French neurologist Duchenne described the progressive muscular atrophy of childhood that now bears his name. However, it was not until the second edition of his famous monograph in 1861 that the “hypertrophic paraplegia of infancy” was recognized as a distinct syndrome. By 1868 he was able to write a comprehensive description of 13 cases and recognized that the disease was muscular in origin and restricted to males. Gowers in 1879 gave a masterful account of 21 personally observed cases and called attention to the characteristic way in which such patients arose from the floor (Gowers sign).

Leyden in 1876 and Möbius 1879 reported a nonhypertrophic form of disease that began in the pelvic girdle muscles and could affect both sexes. Erb, in 1891, crystallized the clinical and histologic concept of a group of diseases due to primary degeneration of muscle, which he called muscular dystrophies. The first descriptions of facioscapulohumeral dystrophy were published by Landouzy and Déjerine in 1894; of progressive ocular myopathy, by Fuchs in 1890; of myotonic dystrophy, by Steinert and by Batten and Gibb in 1909; of distal dystrophy, by Gowers in 1888, Milhorat and Wolff in 1943, Welander in 1951, and Miyoshi et al in 1986; and of oculopharyngeal dystrophy, by Victor, Hayes, and Adams in 1962.

In addition to these classic forms of dystrophy, a number of variant syndromes have come to light. Bramwell in 1922 described hereditary quadriiceps myopathy; Dreifuss in 1961 and Emery in 1966 placed on record a sex-linked humeroperoneal dystrophy; and Seitz in 1957 distinguished a form of scapuloperoneal dystrophy with cardiomyopathy from the larger group of scapuloperoneal syndromes. References to these and other writings of historical importance can be found in the works of Kakulas and Adams, of Walton et al., and of Engel and Franzini-Armstrong (see References).

In the more recent history of the dystrophies, the most notable event has been the discovery by Kunkel, in 1986, of the dystrophin gene and its protein product. Since then there has been an extraordinary accumulation of molecular-genetic, ultrastructural, and biochemical information about the muscular dystrophies, which has greatly broadened our understanding of their mechanisms and causation. It has also clarified a number of uncertainties as to their
clinal presentations and has necessitated a revision of the older conventional classification.

**Duchenne Muscular Dystrophy (Severe Generalized Muscular Dystrophy of Childhood)** (See Table 50-1)

This is the most frequent and best known of the muscular dystrophies. It begins in early childhood and runs a relatively rapid, progressive course. The incidence rate is in the range of 13 to 33 per 100,000 yearly or about one in 3300 live male births in every part of the world. There is a strong familial liability since the disease is transmitted as an X-linked recessive trait, occurring predominantly in males. However, careful examination of their mothers will show slight involvement in as many as half of the so-called mutant cases, as pointed out by Roses and coworkers. Approximately 30 percent of patients have no family history of the disease and represent spontaneous mutations.

Very occasionally, a severe proximal muscular dystrophy occurs in young girls. This may have several explanations: The female may have only one X chromosome, as occurs in the Turner (XO) syndrome and that chromosome carries the Duchenne gene, or the so-called Lyon principle may be operative; i.e., there is inactivation of the unaffected paternal X chromosome allowing expression of the mutated Duchenne protein from the maternal chromosome in a large proportion of embryonic cells. It so happens that most childhood dystrophies in girls prove to be of an entirely different type that is not X-linked and is instead due to an autosomal recessive mutation causing a limb-girdle dystrophy as discussed further on.

**Clinical Features** Duchenne muscular dystrophy is usually recognized by the third year of life and almost always before the sixth year. Nearly half of the patients show evidence of disease before beginning to walk. Many of them are slightly backward in other ways (psychomotor retardation), and the muscle weakness may at first be overlooked. A greatly elevated creatine kinase (CK) may be the first clue. In another group of young children, an indisposition to walk or run normally at the expected time brings them to medical attention; or, having achieved these motor milestones, they appear to be less active than usual and are prone to falls. Increasing difficulty in walking, running, and climbing stairs, swayback, and waddling gait become ever more obvious as time passes. The iliopsoas, quadriceps, and gluteal muscles are involved initially; then the pretibial muscles weaken (foot drop and toe walking). Muscles of the pectoral girdle and upper limbs are affected after the pelvic-crural ones; the serrati, lower parts of pectorals, latissimus dorsi, biceps, and brachioradialis muscles are affected, more or less in the order mentioned.

Enlargement of the calves and certain other muscles is progressive in the early stages of the disease, but most of the muscles, even the ones that are originally enlarged, eventually decrease in size; only the gastrocnemius, and to a lesser extent the lateral vasti and deltoids, are consistently large, and this peculiarity may attract attention before the weakness becomes evident. The enlarged muscles have a firm, resilient (“rubbery”) feel and as a rule are slightly

CMD: childhood muscular dystrophy.
LGMD: limb-girdle muscular dystrophy.
N: normal.
Muscles of the pelvic girdle, lumbosacral spine, and shoulders become weak and wasted, accounting for certain clinical peculiarities. Weakness of abdominal and paravertebral muscles accounts for a lordotic posture and protuberant abdomen when standing and the rounded back when sitting. Bilateral weakness of the external spasticity of the knees and hips interferes with equilibrium and with activities such as climbing stairs or rising from a chair or from a stooped posture. In standing and walking, the patient places his feet wide apart in order to increase his base of support. To rise from a sitting position, he first flexes his trunk at the hips, puts his hands on his knees, and pushes the trunk upward by working the hands up the thighs. In rising from the ground, the child first assumes a four-point position by extending the arms and legs to the fullest possible extent and then works each hand alternately up the corresponding thigh (the sign traditionally attached to Gowers' name). In getting up from a recumbent position, the patient turns his head and trunk and pushes himself sideways to a sitting position S. A. K. Wilson used an alliterative phrase to describe the characteristic abnormalities of stance and gait—the patient “straddles as he stands and waddles as he walks.” The waddle is due to bilateral weakness of the gluteus medius. Many affected boys have a tendency to walk on their toes as a consequence of contractures in the gastrocnemius muscles. Calp pain is not infrequent. Weakening of the muscles that fix the scapulae to the thorax (serratus anterior, lower trapezius, rhomboids) causes a winging of the scapulae, and the scapular angles can sometimes be seen above the shoulders when one is facing the patient.

Later, weakness and atrophy spread to the muscles of the legs and forearms. The muscles that are selectively affected include the neck flexors, wrist extensors, brachioradialis, costal part of the pectoralis major, latissimus dorsi, biceps, triceps, anterior tibial, and peroneal muscles. The ocular, facial, bulbar, and hand muscles are usually spared, although weakness of the facial and sternocleidomastoid muscles and of the diaphragm occurs in the late stages of the disease. As the trunk muscles atrophy, the bones stand out like those of a skeleton. The space between the lower ribs and iliac crests diminishes with affection of the abdominal muscles.

The limbs are usually loose and slack, but as the disability progresses, fibrous contractures appear as a result of the limbs remaining in one position and the imbalance between agonists and antagonists. Early in the ambulatory phase of the disease, the feet assume an equinovarus position due to shortening of the posterior calf muscles, which act without the normal opposition of the pre-tibial and peroneal muscles. Later, the hamstring muscles become permanently shortened because of a lack of counteraction of the weaker quadriceps muscles. Similarly, contractures occur in the hip flexors because of the relatively greater weakness of hip extensors and abdominal muscles. This leads to a pelvic tilt and compensatory lordosis to maintain standing equilibrium. The consequences of these contractures account for the habitual posture of the patient with Duchenne dystrophy: lumbar lordosis, hip flexion and abduction, knee flexion, and plantar flexion. As they become severe, these contractures contribute importantly to the eventual loss of ambulation. Scoliosis, due to unequal weakening of the paravertebral muscles, and flexion contractures of the forearms appear, usually after walking is no longer possible.

The tendon reflexes are diminished and then lost as muscle fibers disappear, the ankle reflexes being the last to go. The bones are thin and demineralized, and the appearance of ossification centers is delayed. Smooth muscles are spared, but the heart is usually affected. Various types of arrhythmia may appear. The electrocardiogram (ECG) shows prominent R waves in the right precordial leads and deep Q waves in the left precordial and limb leads, the result of cardiac fiber loss and replacement fibrosis of the basal part of the left ventricular wall (Perloff et al).

Death is usually the result of pulmonary infections and respiratory failure and, sometimes, of cardiac decompensation. These patients usually survive until late adolescence, and not more than 20 to 25 percent of patients live beyond the twenty-fifth year. The last years of life are spent in a wheelchair; finally the patient becomes bedfast.

Mild degrees of mental retardation, which is nonprogressive, are observed in many cases. The average IQ is 85 but the range has been 40 to 130. Approximately one-quarter have an IQ below 70.

As mentioned earlier, Roses and colleagues have studied the female carriers of the disease (i.e., the mothers of affected boys) and report a slight weakness and enlargement of the calves as well as elevated CK values and abnormalities of the electromyogram (EMG) and muscle biopsy—all slight in degree—in over 80 percent. A small number of female carriers manifest a moderate degree of myopathy that may mimic limb-girdle dystrophy (see further on). The muscle fibers of such patients (referred to as manifesting or symptomatic carriers) show a unique mosaic immunostaining pattern—some fibers containing dystrophin and others lacking it (Hoffman et al). This diagnostic information is particularly helpful in genetic counseling.

The serum CK values are 25 to 200 times normal, which, with the EMG and muscle biopsy findings, help to exclude a hereditary spinal muscular atrophy. The EMG shows fibrillations, positive waves, low-amplitude and brief polyphasic motor unit potentials, and, sometimes, high-frequency discharges. The female carrier may occasionally display the same abnormalities, but to a much milder degree.

The molecular and genetic bases of the disease are discussed further on.

**Becker-Type Muscular Dystrophy**

This well-characterized dystrophy is closely related to the Duchenne type. It had long been noted that mixed with the Duchenne group of cases were certain relatively benign ones. In 1955, Becker and Keiner proposed that the latter be separated as a distinct entity, now called Becker muscular dystrophy. Its incidence is difficult to ascertain, probably 3 to 6 per 100,000 male births. Like the Duchenne form, it is an X-linked disorder, practically limited to males and transmitted by females. It causes weakness and hypertrophy in the same muscles as the Duchenne dystrophy, but the onset is much later (mean age, 12 years; range, 5 to 45 years). While boys with Duchenne dystrophy are usually dependent on a wheelchair by early in the second decade, it is not uncommon for those with Becker dystrophy to walk well into adult life. We have, for example, encountered patients who served in the military with the disease undetected. If maternal uncles are affected by the disease and are still walking, the diagnosis is relatively easy. Mentation is usually normal. Cardiac involvement is also less frequent than in Duchenne dystrophy but there are cases that present with cardiomyopathy, and we have been made aware of two brothers who had cardiac
transplantation before the disease was detected. Kuhn and associates have reported a genealogy in which early myocardial disease and cramping myalgia were prominent features.

Pathology of Duchenne and Becker Dystrophies In the early stages of Duchenne dystrophy, the most distinctive features are prominent segmental degeneration and phagocytosis of single fibers or groups of fibers and evidence of regenerative activity (basophilia of sarcoplasm, hyperplasia and nucleolation of sarcosomal nuclei, and the presence of myotubes and myocytes). The necrosis excites a regenerative or restorative process, which explains the forking of fibers and clustering of small fibers with prominent nuclei. The necrotic sarcoplasm and sarcolemma are removed by mononuclear phagocytic (macrophage) cells. There may also be a few T lymphocytes in the region suggesting inflammation. The blood vessels are normal. There is a hyalinization of the sarcoplasm of many degenerating and nondegenerating fibers. In longitudinal sections, these are seen as "contraction bands," expressive of the irritability of dystrophic muscle. This phenomenon may be present before there is any significant degree of degeneration and is more extensive in Duchenne than in any of the other dystrophies. Eventually there are histologic changes that are common to all types of advanced muscular dystrophies: loss of muscle fibers, residual fibers of larger and smaller size than normal—all in haphazard arrangement, and the secondary reaction of an increase in lipocytes and fibrosis.

Hypertrophy of muscle is believed to be a result of work-induced enlargement of the remaining sound fibers in the face of adjacent fiber injury. But examples of true hypertrophy of entire muscles prior to the first sign of weakness may also occur and are difficult to explain. In these cases, large fibers may be present when at most there are only a few degenerating fibers. Pseudohypertrophy is due to lipocytic replacement of degenerated muscle fibers, but in its earlier stages the presence of many enlarged fibers contributes importantly to the enlargement of muscle, all secondary changes. Thus a true hypertrophy appears to give way to pseudohypertrophy. Smallness of residual fibers (possibly atrophy) is a prominent histologic feature. It is uncertain if this represents a gradual failure of cell metabolism and reduction in volume of all sarcoplasmic constituents or a stage in the regeneration of the damaged muscle fiber. The fibers do eventually degenerate and disappear, owing presumably to an exhaustion of regenerative capacity after repeated injuries or more and more extensive necrosis. In the late stage of the dystrophic process, only a few scattered muscle fibers remain, almost lost in a sea of fat cells. It is notable that the late or burned-out stage of chronic polymyositis resembles muscular dystrophy in that the fiber population is depleted, the residual fibers are of variable size, and fat cells and endomyosial fibrous tissue are increased; lacking only are the hypertrophied fibers of dystrophy. This resemblance confirms that many of the typical changes of muscular dystrophy are nonspecific, reflecting only the chronicity of the myopathic process.

Etiology of Duchenne and Becker Dystrophies The most important development in our understanding of the Duchenne and Becker muscular dystrophies was the discovery by Kunkel of the abnormal gene on the X chromosome and of its gene product, dystrophin (Hoffman et al). The protein is expressed in skeletal, cardiac, and smooth muscle as well as in brain. The dystrophin gene is to date the largest one known, spanning more than 2 Mb of genomic DNA. This is the likely explanation for the observation that one third of affected boys have a spontaneous mutation in the gene that is not inherited from their mother. The biochemical assay of dystrophin and its histochemical demonstration near the sarcolemma have made possible the accurate diagnosis of the Duchenne and Becker phenotypes and have clarified the relationship between these two disorders. Whereas dystrophin is absent in patients with the Duchenne phenotype, it is present but structurally abnormal in the Becker type. Moreover, phenotypes that falls between the classic Duchenne and Becker forms (intermediate or "outlier" cases) are characterized by a lower than normal amount of dystrophin. The Duchenne and Becker dystrophies and their intermediate forms are spoken of as dystrophinopathies.

A slightly different form of dystrophin, originating in a different part of the gene, is found in neurons of the cerebrum and brainstem and in astrocytes, Purkinje cells, and Schwann cells, at nodes of Ranvier (Harris and Cullen). A deficiency of the cerebral dystrophin may in some yet unexplained way account for the mild mental retardation. It will be interesting to learn how such a deficiency might impair brain development and whether there is any connection to some cases of mental deficiency without muscular dystrophy.

Figure 50-1 is useful in understanding the pathogenesis of the dystrophinopathies and certain of the limb-girdle and congenital dystrophies described further on. In normal skeletal and cardiac muscle, dystrophin is localized to the cytoplasmic surface of the sarcolemma, where it interacts with F-actin of the cytoskeleton (the filamentous reinforcing structure of the muscle cell). Dystrophin is also tightly bound to a complex of sarcolemmal proteins, known as dystrophin-associated proteins (DAPs), and glycoproteins (DAGs). Of special biologic importance in this complex are these two proteins and a 156-kDa glycoprotein called dystroglycan. The latter actually lies just outside the muscle cell and links the sarcolemmal membrane to the extracellular matrix (the inner portion of the basement membrane) by binding with merosin, a subunit of laminin. The dystrophin-glycoprotein complex functions in this scheme as a transsarcolemmal structural link between the subsarcolemmal cytoskeleton and the extracellular matrix. Moreover, all the associated membrane-binding proteins (adhalin, merosin, laminin) are implicated in specific muscular dystrophies, as discussed later in the chapter.
CHAPTER 50   THE MUSCULAR DYSTROPHIES

The loss of dystrophin leads to a parallel loss of DAPs and to disruption of the dystroglycan-protein complex. This change renders the sarcolemma susceptible to breaks and tears during muscle contraction—a hypothesis proposed first by Mokri and Engel and entirely consistent with the ultrastructural abnormalities that characterize Duchenne dystrophy. These authors demonstrated defects of the plasma membrane (sarcolemma) in a large proportion of nonnecrotic hyalinized muscle fibers, allowing ingress of extracellular fluid and calcium. The entrance of calcium is speculated to activate proteases and to increase protein degradation. The membrane defects and the associated alterations in the underlying region of the fiber represent the earliest and most basic pathologic change in Duchenne dystrophy and account for the leakage into the serum of CK and other enzymes of muscle.

Diagnosis   The identification of dystrophin has made possible a number of highly refined tests for the diagnosis of Duchenne and Becker dystrophies, as well as for the carrier state. For example, analysis of the dystrophin gene in DNA obtained from white blood cells or from 50 mg of skeletal muscle can demonstrate the gene mutations in Duchenne and Becker patients and discriminate between these diseases with great accuracy. Also, immunostaining of muscle for dystrophins makes possible the differentiation of Duchenne, Becker, the carrier state, and other muscle disorders. An alternative method, developed by Byers and colleagues, employs an enzyme-linked immunosorbent assay (ELISA) to measure the dystrophin levels in muscle biopsy samples. This testing is a rapid and relatively inexpensive tool for establishing the diagnosis of Duchenne and Becker muscular dystrophies and distinguishing them from unrelated disorders.

Other Dystrophinopathies   Refined testing for the dystrophin protein has also brought to light several much rarer types of dystrophin abnormalities. One, described by Gospe and coworkers (1972) are variants of Emery-Dreifuss muscular dystrophy. The primary gene defect is a deficiency of the protein emerin, encoded by a gene on the X chromosome. Emerin is a constituent of the nuclear membrane (Fig. 50-2).

The age of onset varies from childhood to late adolescence or adulthood. Weakness affects first the upper arm and pectoral girdle musculature and later the pelvic girdle and the distal muscles in the lower extremities. A consistent and distinguishing feature of the disease is the early appearance of contractures in the flexors of the elbow, extensors of the neck, and posterior calf muscles. Facial muscles are affected occasionally. There is no hypertrophy or pseudohypertrophy, and mentation is unaffected. A severe cardiomyopathy with variable sinoatrial and atrioventricular conduction defects is a common accompaniment. The course of the myopathy is generally benign, more like that of Becker dystrophy, but weakness and contractures are severe in some cases, and sudden cardiac death is a not infrequent occurrence. For this reason, close monitoring by a cardiologist and the prophylactic insertion of a pacemaker at the appropriate time may be life-saving.

It has been proposed, but not proven, that the X-linked scapuloperoneal muscular atrophy with cardiopathy (Mawatari and Katayama) and the X-linked scapuloperoneal syndrome described by Thomas and coworkers (1972) are variants of Emery-Dreifuss dystrophy. The latter disorder, like Emery-Dreifuss dystrophy, is due to an abnormality of emerin. A humeroperoneal myopathy described by Gilchrist and Lesher is phenotypically much the same as the Emery-Dreifuss syndrome, though it is genetically distinct, being inherited as an autosomal dominant trait.

Faciescapulohumeral (FSH) Muscular Dystrophy (Landouzy-Déjerine Muscular Dystrophy) (See Table 50-2)

This is a slowly progressive dystrophy involving primarily the musculature of the face and shoulders, often with long periods of nearly complete arrest. The pattern of inheritance is usually autosomal dominant.

While less common than the Duchenne and myotonic dystrophies, this disease is not rare (an estimated yearly incidence rate of 5:100,000) and we see one or more new cases yearly. The age of onset is usually between 6 and 20 years but cases beginning in early adult life are occasionally encountered. As a rule, the first manifestations are difficulty in raising the arms above the head and winging of the scapulae, although in many cases bifacial weakness may have initially attracted attention, even in early childhood. There is involvement especially of the orbitalis oculi, the zygomaticus, and the orbicularis oris, whereas the masseters as well as the temporalis, extraocular, pharyngeal, and respiratory muscles...

CTG: cytosine, thymine, guanidine.
GCG: guanidine, cytosine, guanidine.

are spared. Weakness and atrophy of the involved muscles are the major physical findings; pseudohypertrophy occurs only rarely and is slight. There is an inability to close the eyes firmly, to purse the lips, and to whistle; the lips have a peculiar looseness and tendency to protrude. The lower parts of the trapezius muscles and the sternal parts of the pectorals are almost invariably affected. By contrast, the deltoids may seem to be unusually large and strong, an appearance that may be mistaken for pseudohypertrophy. The advancing atrophic process involves the sternocleidomastoid, serratus magnus, rhomboideus, erector spinae, latissimus dorsi, and eventually the deltoid muscles. The bones of the shoulders become prominent; the scapulae are winged and elevated ("angel-wing" appearance), and the clavicles stand out. The anterior axillary folds slope down and out as a result of wasting of the pectoral muscles. Usually the biceps waste less than the triceps, and the brachioradialis muscles even less, so that the upper arm may be thinner than the forearm ("Popeye" effect). Pelvic muscles are involved later and to a milder degree, giving rise to a slight lordosis and pelvic instability. The pretribital muscles weaken, and foot drop is added to the waddling gait. Beevor’s sign, an upward movement of the umbilicus on flexing the neck due to weakness of the lower abdominal muscles, is reportedly common (Awerbuch et al) but we have not seen it in early cases.

Early in the disease, the muscular weakness may be asymmetrical (winging of only one scapula). Many of the patients with milder degrees of this form of dystrophy are unaware that they have the disease. This was true of nearly half of the very large series of patients described by Tyler and Stephens in the Utah Mormon population. At any point, the disease may become virtually arrested. Nevertheless, 15 to 20 percent of patients eventually require a wheelchair (Tawil et al).

An occasional feature of this group of diseases is the congenital absence of a muscle (one pectoral, brachioradialis, or biceps femoris) or part of a muscle in patients who later develop the typical features of FSH. Also, the external ocular muscles are known to occasionally become affected late in the illness. Cardiac involvement is rare, but in a few of the cases tachycardia, cardiomegaly, and arrhythmias (ventricular and atrial extrasystoles) have occurred. Mental function is normal. Serum CK values are normal or slightly elevated.

At a molecular level, facioscapulohumeral dystrophy has been found to have a consistent association with deletions of variable size on the tip of chromosome 4q. This disorder is a consequence of alterations of a noncoding portion of DNA. It has been postulated that the deletions interfere with the expression of a gene or genes located proximal to the deletions (see Tawil et al) or that they alter the conformation of chromosome 4 within the nucleus, thereby affecting gene expression.

A variant in which only the shoulder and arm muscles are affected, sparing the face, and a form with bilateral foot drop are known (Krasnianski et al). In some cases, usually with severe deletions at the FSH locus on chromosome 4, there is an early onset and relatively rapid progression and an association with facial diplegia, sensorineural deafness, and, sometimes, exudative retinal detachment (Coats disease). Using fluorescein angiography, Fitzsimmons and others have found a variety of other retinal abnormalities—telangiectases, occlusion, leakage, and microaneurysms—in 56 of 75 persons with the usual form of facioscapulohumeral dystrophy, suggesting that these retinal abnormalities are an integral part of the disease. Other subtypes of FSH are linked to the same genetic site as the classic disease, including a face-sparing variant and a completely unexpected phenotype with progressive external ophthalmoplegia.

Scapuloperoneal Muscular Dystrophy

Beginning with Brossard in 1886, there were numerous reports of a distinctive pattern of progressive muscular weakness and wasting that typically involves the muscles of the neck, shoulders, and upper arms and anterior tibial and peroneal groups, causing foot drop. The nature of this disorder has been a matter of controversy, some writers claiming it to be a progressive muscular dystrophy and others, a muscular atrophy of spinal or neuropathic type. Probably both are correct in that either process can produce more or less the
same pattern of weakness. Davidenkow, who wrote extensively on this subject, described a form of familial scapuloperoneal weakness and atrophy associated with areflexia and distal sensory loss (a spinal-neuronopathic form), and others have confirmed these findings (see discussions of Thomas et al and of Munsat and Serrathlete). Nevertheless, Thomas and colleagues (1975) firmly established the existence of a purely myopathic form. The onset of symptoms in their 6 patients was in early or middle adult life, with difficulty in walking due to bilateral foot drop; symptoms referable to scapulo-humeral involvement came later. Progression was slow and none of the patients became severely incapacitated. Autosomal dominant inheritance seemed likely.

More recently, Wilhelmse and associates have described a large family with autosomal dominant scapuloperoneal myopathy (14 affected persons in a 44-member pedigree). Onset was in early adult life with difficulty in walking and climbing stairs, due to foot drop, followed by weakness of the proximal arm muscles. In 3 individuals from this family, the disease was relentlessly progressive, but in the others it was relatively benign. In addition to the nonspecific histologic features of muscular dystrophy, some fibers contained eosinophilic hyaline inclusions and rimmed vacuoles. Linkage analysis has localized the gene to chromosome 12, proving that it is not simply an allelic variant of facioscapulohumeral or one of the other types of muscular dystrophy. It is now clear that there is some molecular heterogeneity in these cases, as other pedigrees link to chromosome 3.

### Limb-Girdle Muscular Dystrophies (LGMD: Scapulohumeral and Pelvifemoral Muscular Dystrophies, Erb Dystrophy) (See Table 50-1)

There is a large group of patients with muscular dystrophy who do not fit into the Duchenne/Becker, facioscapulohumeral, or scapuloperoneal categories previously described. Children of both sexes in this group lack the hypertrophy of calves and other muscles; adults with late-onset forms have either pelvic or shoulder girdle involvement or both, and their facial muscles are spared. Insofar as Wilhelm Erb first called attention to these types of dystrophy, they were classified by Walton and Nattrass as the “limb-girdle dystrophies of Erb.” This clinically based grouping has been problematic from the time it was proposed because, like the scapuloperoneal group, it is heterogeneous—the only unifying feature being the presence of limb-girdle weakness with sparing of the facial muscles. The inheritance has been variable, but the autosomal recessive forms are the most common. Either the shoulder girdle or pelvic girdle muscles may be first affected (traditionally these forms had been referred to as the Erb juvenile atrophic and Leyden-Möbius types, respectively). The weakness and atrophy may become evident during either late childhood or early adult life and spread from shoulders to hips or vice versa.

The later the onset of these disorders, the more likely that the course will be benign. In the latter group, while the EMG is myopathic, the CK values are only moderately elevated and may even be normal in the most chronic forms. Cardiac involvement is infrequent, and mental function is normal.

As indicated earlier, the status of this group of limb-girdle dystrophies as a clinical-genetic entity is being steadily eroded. The delineation of the progressive spinal muscular atrophies and the congenital and metabolic myopathies has considerably narrowed the category of limb-girdle dystrophies as originally described.

During the past decade, with the application of molecular genetic techniques, progress in this direction has accelerated greatly. At the time of this writing, at least 5 forms of autosomal recessive (LGMD type 2), 5 forms of autosomal dominant (LGMD type 1), and 10 forms of autosomal recessive (LGMD type 2) limb-girdle dystrophies have been defined—most with a distinct chromosomal locus and, 7 of them with an identifiable protein gene product that in most cases turns out to be a constituent of the muscle membrane (Bushby). This information is summarized in Table 50-1, and discussion of the better-characterized types follow.

#### Limb-Girdle Muscular Dystrophy 2I (Fukutin-Related Protein Mutation) The discovery of the “fukutin-related protein” initially came about because mutant forms cause a severe congenital muscular dystrophy. However, it became apparent that certain mutations also cause a common type of later-onset limb-girdle dystrophy. As the designation “2” indicates, it is transmitted in an autosomal recessive manner. In a series of 16 patients from 14 families, Poppe and colleagues have tried to characterize the main features. The onset of proximal girdle weakness occurs mainly in the second to fourth decades, but as early as age 2 years. The majority of patients eventually had respiratory failure and several had congestive heart failure, features that accompany some of the other limb-girdle dystrophies. In most other ways, this disease reflects the heterogeneity of clinical presentation of the other subtypes of limb-girdle disease. A period of stabilization or muscular power lasting several to 35 years is common, followed by a decade or more of progression that eventually involves the shoulder muscles. Most patients, particularly those with later onset, remained able to walk into their forties. Other features are variable, for example, dysphagia and ptosis; however, distal weakness is not seen and intelligence is normal.

The defective FKRP gene is located on chromosome 19q13.3. It is related in function to four other muscle genes including fukutin (hence its name). All five of these genes are glycosyl transferases that attach sugar groups to proteins such as alpha-dystroglycan. In all, the severity of the clinical phenotype is inversely related to the levels of glycosylation of alpha-dystroglycan. Defects in any of the five genes can cause developmental lesions in the brain in addition to muscle disease, although those associated with FKRP mutations are less common and less severe.

### Severe Childhood Autosomal Recessive Muscular Dystrophy (SCARM: Sarcoglycanopathy; LGMD 2C, D, E, and F; See Table 50-1) These entities comprise the best-defined group of limb-girdle dystrophy. Clinically they resemble severe Duchenne dystrophy in practically all respects, including the presence of calf hypertrophy, cardiomyopathy, and marked elevation of CK in the early stages of the illness. The obvious distinction from Duchenne dystrophy is the autosomal recessive pattern of inheritance (affection of both girls and boys in the same sibship). The largest and best-studied group of this severe, recessive pelvic-pectoral dystrophy (99 children in 28 families), has come from Tunisia (Ben Hamida et al). It also occurs commonly in other Arab countries and has been observed repeatedly in Brazil and less so in Europe and North America.

The basic defect is in one of four dystrophin-associated glycoproteins (DAGs)—α-, β-, γ- and δ-sarcoglycan (see Fig. 50-1); α-sarcoglycan (designated 50 DAG) is also called adhalin, from the Arabic word adhal, meaning muscle. A primary deficiency of adhalin has been traced to a defective gene on chromosome 17q21 (Roberds et al). A primary defect in β-sarcoglycan (43 DAG) has
been mapped to chromosome 4q12, of γ-sarcoglycan (35 DAG) to the pericentromeric region of chromosome 13q, and of β-sarcoglycan (35 DAG) to chromosome 5q. Primary defects in 43 DAG or 25 DAG, may in addition lead to a deficiency of adhalin, but the latter is incomplete and represents a secondary effect, possibly explained by the proximity of the defective genes to the adhalin gene.

From a practical point of view, despite clinical similarities, there is usually no serious difficulty in distinguishing these dystrophies (formerly termed SCARMID) from a dystrophinopathy. In addition to the difference in inheritance, they can be readily diagnosed by showing a loss of sarcolemmal immunostaining for any of the dystrophin-associated glycoproteins but with preservation of staining for dystrophin itself. However, it is not possible on clinical grounds to distinguish one sarcoglycanopathy from another; this can be accomplished only by specific immunostaining.

Autosomal Recessive Muscular Dystrophy Linked to Chromosomes 15q and 2p (LGMD 2A and B; Calpain Mutation; See Table 50-1) These forms of limb-girdle dystrophy have been described in several large kindreds, in Indiana (among the Amish people), on the island of Réunion in the Indian Ocean, and in Brazil, affecting males and females equally. Both the shoulder and pelvic girdles are involved. The degree of weakness has varied considerably. In one form of the disease, called LGMD 2A, the abnormal gene codes for a calcium-activated neutral protease, or calpain. This “calpainopathy” is currently believed to account for about 40 percent of patients with LGMD. Frequently, and early in the course of disease, there are Achilles tendon contractures and very high serum CK levels (at least 10 times normal)—features that may permit distinction from the sarcoglycanopathies.

Yet another recessive limb-girdle dystrophy of slow progression has been identified in a Palestinian and Sicilian family and is due to a mutation in the gene for the protein dysferlin, which localizes to the muscle fiber membrane. Noteworthy is the fact that this same protein is involved in the distal form of Miyoshi muscular dystrophy described further on (page 1223). Early involvement of the gastrocnemius muscle (inability to walk on tiptoe) and extraocular muscles permits the eyes to remain in a central position, so that strabismus and diplopia are uncommon (in rare instances one eye is affected before the other). The pupillary responses and accommodation are normal. As the patient attempts to raise his eyelids and to see under them, the head is thrown back and the frontalis (hutchinsonian facies) weakness but neither the weakness nor the contractures were disabling. Unlike Emery-Dreifuss dystrophy, contractures of the neck and spine were not present. Uniformity of clinical expression, slow progression with long periods of arrest, and normal longevity are other important features of the illness. Mohire and coworkers have proposed the designation Bethlem myopathy. A similar disease has now been reported from many parts of the world. Linkage analysis has assigned the gene locus of this myopathy to the subunits of a collagen gene on chromosomes 2 and 21. Another group of similarly affected Dutch families described by van der Kooi and coworkers also displayed an autosomal dominant pattern of inheritance. Clinically the latter dystrophy is much the same as described by Bethlem, except that more than half of the affected members develop abnormalities of cardiac rhythm in their later years necessitating pacemaker implantation. In contrast to the Bethlem cases, the gene abnormality is on chromosome 1q.

Autosomal Dominant Limb-Girdle Dystrophies (See Table 50-1) Several dystrophies with the LGMD phenotype are inherited as autosomal dominant traits. For example, LGMDA 1A is an autosomal dominant limb-girdle dystrophy of late onset that was described in a large North Carolina family (49 affected members in a pedigree of 218 persons). The mean age at onset was 27 years. Proximal leg weakness, with or without proximal arm weakness, and elevated CK values were the main clinical characteristics. Speer and colleagues have documented that the primary defect is in a gene encoding the protein myotilin (see Fig. 50-2).

LGMD 1B is a dominantly inherited disorder arising from mutations in the gene encoding the nuclear membrane protein lamin A/C (see Fig. 50-2). Mercuri and colleagues note that the phenotypes of these mutations vary widely. The muscle disorders range from severe cases that mimic congenital muscular dystrophy to milder ones with features of limb girdle dystrophy or Emery-Dreifuss muscular dystrophy. The diverse, nonmuscular manifestations of lamin A/C mutations include cardiomyopathy, a form of lipodystrophy, a syndrome of accelerated aging (Hutchinson-Gilford progeria), and a recessively inherited axonal neuropathy.

Preceding these genetic findings, in 1976, Bethlem and van Wijngaarden described an autosomal dominant, early-onset limb-girdle dystrophy in 28 members of three unrelated Dutch families. Flexion contractures of the elbows, ankles, and interphalangeal joints of the fingers were present from the beginning stages of weakness but neither the weakness nor the contractures were disabling. Unlike Emery-Dreifuss dystrophy, contractures of the neck and spine were not present. Uniformity of clinical expression, slow progression with long periods of arrest, and normal longevity are other important features of the illness. Mohire and coworkers have proposed the designation Bethlem myopathy. A similar disease has now been reported from many parts of the world. Linkage analysis has assigned the gene locus of this myopathy to the subunits of a collagen gene on chromosomes 2 and 21. Another group of similarly affected Dutch families described by van der Kooi and coworkers also displayed an autosomal dominant pattern of inheritance. Clinically the latter dystrophy is much the same as described by Bethlem, except that more than half of the affected members develop abnormalities of cardiac rhythm in their later years necessitating pacemaker implantation. In contrast to the Bethlem cases, the gene abnormality is on chromosome 1q.
of cases. The characteristic feature of progressive external ophthalmoplegia is that ptosis and ocular paralysis precede involvement of other muscles by many years.

Opinions had varied as to whether all cases of progressive external ophthalmoplegia should be assigned a myopathic origin. First, dystrophy and partial denervation of these muscles are difficult to distinguish on the basis of the biopsied eye muscle, as was pointed out by Ringel and associates. (Denervation of eye muscles does not result in a clearly visible grouped atrophy pattern.) The myopathic origin of some cases is proven by intactness of neurons in the brainstem nuclei and normality of the cranial nerves. Genetic studies have defined the molecular basis for some cases of the dominantly inherited PEO. Given that there is considerable clinical overlap between Kearns-Sayre syndrome and dominantly inherited PEO, it is not surprising that some of the dominantly inherited gene defects causing PEO result in disturbances in mitochondria DNA. Mutations in three nuclear genes have been implicated. (These are twinkle, a mitochondrial DNA binding protein; ANT1, an adenine nucleotide transporter in the intermembrane space in the mitochondrial; and POLG, a subunit of the mitochondrial DNA polymerase.) There are also recessively inherited instances of familial PEO, one of which involves a nuclear gene.

**Oculopharyngeal Dystrophy**

(See Table 50-2)

Oculopharyngeal dystrophy is inherited as an autosomal dominant trait and is unique in respect to its late onset (usually after the 45th year) and the restricted muscular weakness, manifest mainly as a bilateral ptosis and dysphagia. E. W. Taylor first described the disease in 1915 and assumed that it was due to a nuclear atrophy (oculomotor-vagal complex). However, Victor and colleagues, in 1962, showed that the descendants of Taylor’s cases had a late-life dystrophy (myopathic EMG and biopsy). One of the families described by Victor and Adams was subsequently traced by Barbeau through 10 generations to an early French-Canadian immigrant, who was the progenitor of 249 descendants with the disease. Other families showing a dominant (rarely recessive) pattern of inheritance were also described by Victor and others. (Denervation of eye muscles was an example of this disease, differing from the simple distal muscular dystrophy described later by Welander and others (see further on).

Despite some clinical variability of myotonic dystrophy, the defective gene has been the same in every population that has been studied. At this locus on chromosome 19q there is a specific molecular defect—an unstable trinucleotide sequence (CTG) that is longer in affected individuals than in healthy siblings or unaffected control subjects. Whereas healthy individuals will have 5 to 30 CTG repeats, patients with myotonic dystrophy have 50 to 2000. Longer sequences are associated with more severe disease, and increases in size through successive generations leads to earlier occurrence (genetic anticipation). The CTG repeats reside within the myotonin protein kinase gene. It is of considerable interest that these CTG repeating segments do not code for a protein (i.e., they are intronic), quite unlike conditions such as Huntington disease in which the triplet expansion codes for amino acid sequences within a protein. A critical element in the pathogenesis of this disease is the intranuclear accumulation of the expanded RNA sequences; these are believed to alter RNA binding proteins, thereby perturbing the expression of many genes.

**Clinical Features**

In most instances of myotonic dystrophy the weakness and muscular wasting does not become evident until early adult life but it may present in childhood, usually with facial weakness and ptosis. Also, a severe, neonatal (congenital) form of the disease is well known and is described separately further on.

In the common early-adult form of the disease, the small muscles of the hands along with the extensor muscles of the forearm are often the first to become atrophied. In other cases, ptosis of the eyelids and thinness and slackness of the facial muscles may be the earliest signs, preceding other muscular involvement by many years. Atrophy of the masseters leads to narrowing of the lower half of the face, and the mandible is slender and malpositioned so that the teeth do not occlude properly. This—along with the ptosis, frontal baldness, and wrinkled forehead—implies a distinctive physiognomy that, once seen, can be recognized at a glance (“hatchet” face). The sternocleidomastoids are almost invariably thin and weak and are associated with an exaggerated forward curvature of the neck (“swan neck”). Atrophy of the anterior tibial
muscle groups, leading to foot drop, is an early sign in some families.

Pharyngeal and laryngeal weakness results in a weak, monotonous, nasal voice. The uterine muscle may be weakened, interfering with normal parturition, and the esophagus is often dilated because of loss of muscle fibers in the striated as well as smooth muscle parts. Megacolon occurs in some patients. Diaphragmatic weakness and alveolar hypoventilation, resulting in chronic bronchitis and bronchiectasis, are common late features, as are cardiac abnormalities; the latter are most often due to disease of the conducting apparatus, giving rise to bradycardia and a prolonged P-R interval. Patients with extreme bradycardia or high degrees of atrioventricular block may die suddenly; for such individuals, insertion of a pacemaker is often recommended (Moorman et al). Mitral valve prolapse and left ventricular dysfunction (cardiomyopathy) are less frequent abnormalities. In this disorder, as in Emery-Dreifuss dystrophy, careful assessment by a knowledgeable cardiologist is required.

The disease progresses slowly, with gradual involvement of the proximal muscles of the limbs and muscles of the trunk. Tendon reflexes are lost or much reduced. Contracture is rarely seen, and the thin, flattened hands are consequently soft and pliable. Most patients are confined to a wheelchair or bed within 15 to 20 years of the first signs, and death occurs before the normal age from pulmonary infection, heart block, or heart failure.

The phenomenon of myotonia, which expresses itself in prolonged idiomuscular contraction following brief percussion or electrical stimulation and in delay of relaxation after strong voluntary contraction, is the third striking attribute of the disease (the other two being the facial, ptotic and limb weakness, and the cardiac-autoimmune features). Not as widespread or severe as in myotonia congenita (Thomsen disease—see page 1265), it is, nonetheless, easily elicited in the hands and tongue in almost all cases and in the proximal limb muscles in half of the cases. Gentle movements do not evoke it (eye blinks, movements of facial expression, and the like are not impeded), whereas strong closure of the lids and clenching of the fist are followed by a long delay in relaxation.

Myotonia may precede weakness by several years. Indeed, Maas and Paterson have claimed that many cases diagnosed originally as myotonia congenita eventually proved to be examples of myotonic dystrophy. Of interest is the fact that in congenital or infantile cases of myotonic dystrophy, the myotonic phenomenon is not elicited until later in childhood, after the second or third year of life (see later). Moreover, the patient often becomes accustomed to the myotonia and does not complain about it. The relation of myotonia to the dystrophy is not direct. Certain muscles that show the myotonia best (tongue, flexors of fingers) are seldom weak and atrophic. Moreover, there may be little or no myotonia in certain families that show the other characteristic features of myotonic dystrophy. The muscle hypertrophy that is characteristic of myotonia congenita is not a feature of myotonic dystrophy.

The fourth major characteristic is the association of dystrophic changes in nonmuscular tissues. The most common of these are lenticular opacities, which are found by slit-lamp examination in 90 percent of patients. At first dust-like, they then form small, regular opacities in the posterior and anterior cortex of the lens just beneath the capsule; under the slit lamp they appear blue, blue-green, and yellow and are highly refractile. Microscopically, the crystalline material (probably lipids and cholesterol, which cause the iridescence) lies in vacuoles and lacunae among the lens fibers. In older patients a stellate cataract slowly forms in the posterior cortex of the lens.

Mild to moderate degrees of mental retardation are not infrequent, and the brain weight in several of our patients was 200 g less than in normals of the same age. Late in adult life, some patients become suspicious, argumentative, and forgetful. In some families, a hereditary sensorimotor neuropathy may be added to the muscle disease (Cros et al).

Other nonspecific abnormalities, such as hyperostosis of the frontal bones and calcification of the basal ganglia, both readily discerned by CT scanning, seem to be more common in patients with myotonic dystrophy than they are in healthy persons.

Progressive frontal alopecia, beginning at an early age, is a characteristic feature in both men and women with this disease. Testicular atrophy with androgenic deficiency, reduced libido or impotence, and sterility are frequent manifestations. In some patients gynecomastia and elevated gonadotropin excretion are found. Testicular biopsy may show atrophy and hyalinization of tubular cells and hyperplasia of Leydig cells. Thus all the clinical characteristics of the Klene-felter syndrome may be present. However, the nuclei of skin or bone marrow cells only rarely show the “sex chromatin” mass (Barr body). The majority of patients have the usual sex chromatin constitution. Ovarian deficiency occasionally develops in the female patient but is seldom severe enough to interfere with menstruation or fertility. The prevalence of clinical or chemical diabetes mellitus is only slightly increased in patients with myotonic dystrophy, but an increased insulin response to a glucose load has proved to be a common abnormality. Numerous surveys of other endocrine functions have yielded rather little of significance.

In an extensive clinical experience with this form of dystrophy, we have been impressed with the variability of its clinical expression. In many patients, intelligence has been unimpaired and the myotonia and muscle weakness have been so mild that the patients were unaware of any difficulty. Pryse-Phillips and associates emphasized these features in their description of a large Labrador kinship in which 27 of 133 patients had only a partial syndrome and only minor muscle symptoms at the time of examination.

Pathologic Features In addition to displaying most of the common findings of muscular dystrophy, there are several highly unusual myopathologic features. Peripherally placed sarcoplasmic masses and circular bundles of myofibrils (ringbinden) are common. Central nucleation may be marked. In many of the muscle spindles there is an excess of intrafusral fibers (particularly in the congenital form, see later). In addition, one observes necrosis of single muscle fibers and many atrophic fibers. Many of the terminal arborizations of the peripheral nerves are unusually elaborate and elongated. The spindle and nerve changes may be secondary to the myotonia or to an as yet poorly characterized associated terminal neuropathy.

Congenital Myotonic Dystrophy Brief reference was made earlier to this distinctive and potentially lethal form of myotonic dystrophy. Its not infrequent occurrence is evident from Harper’s (1975) study of 70 personally observed patients and 56 others gathered from the medical literature. Profound hypotonia and facial diplegia at birth are the most prominent clinical features; myotonia, however, is notable for its absence. The drooping of the eyelids, the tented upper lip (“carp” mouth), and the open jaw impart a
characteristic appearance, which allows immediate recognition of the disease in the newborn infant and child. Difficulty in sucking and swallowing, bronchial aspiration (due to palatal and pharygeal weakness), and respiratory distress (due to diaphragmatic and intercostal weakness and pulmonary immaturity) are present in varying degrees of severity; the latter disorders are responsible for a previously unrecognized group of neonatal deaths (24 such deaths among siblings of affected patients in Harper’s study). In surviving infants, delayed motor and speech development, swallowing difficulty, mild to moderately severe mental retardation, and talipes or generalized arthrogryposis are common. Once adolescence is attained, the disease follows the same course as the later form. As stated earlier, clinical myotonia in the congenital form of the disease becomes evident only later in childhood, although EMG study may disclose myotonic discharges in early infancy. The diagnosis may be suspected by the simple test of eliciting myotonia in the mother. Electrocardiographic changes occur in one-third of the patients.

In the congenital form of this disease the affected parent is always the mother, in whom the disease need not be severe. Electrophysiologic testing will bring out the myotonia in the mother if it is inviduous on percussion of muscle. (In cases of adult onset, transmission is maternal or paternal.) These data suggest that in addition to inheriting the myotonic dystrophy gene, the congenital cases also receive some maternally transmitted factor, the nature of which is presently unknown. The prenatal diagnosis of myotonic dystrophy is readily accomplished by examination for CTG repeats in the amniotic fluid or in a biopsy of chorionic villi. However, it is not possible to predict whether a fetus with an expanded mutation will have congenital myotonic dystrophy or later onset myotonic dystrophy.

**Proximal Myotonic Myopathy (PROMM; See Table 50-2)** Under this name, Ricker and colleagues have described a myopathy characterized by autosomal dominant inheritance, proximal muscle weakness, myotonia, and cataracts. Seventeen families, containing 50 affected members, have been studied by these authors. Onset was between 20 and 40 years, with intermittent myotonic symptoms of the hands and proximal leg muscles, followed by a mild, slowly progressive weakness of the proximal limb muscles without significant atrophy. Cataracts developed in one half the patients and cardiac arrhythmias in only two. Onset in infancy; ptosis; weakness of facial, jaw, and distal limb muscles; and mental abnormalities were notably absent, thereby distinguishing PROMM from the conventional form of myotonic dystrophy.

Histologically the appearance was that of a nonspecific myopathy, without ringbinden or subsarcolemmal masses. Analysis of leukocyte and muscle DNA discloses no expansion of the CTG component of the myotonic dystrophy gene. Rather, the gene defect for this disease has been mapped to chromosome 3q where there is an expansion of a CCTG repeat. Like the expanded CTG repeat in myotonic dystrophy, the CCTG expansion in PROMM is associated with intranuclear accumulation of the expanded RNA transcript and like the CTG repeats of myotonic dystrophy, the CCTG segments do not code for a protein.

**The Distal Muscular Dystrophies (Weland, Miyoshi Types) (See Table 50-3)** Included in this group are several slowly progressive distal myopathies with onset principally in adult life. Weakness and wasting of the muscles of the hands, forearms, and lower legs, especially the extensors, are the main clinical features. Although such cases had been reported by Gowers and others, their differentiation from myotonic dystrophy and peroneal muscular atrophy was unclear until relatively recently.

Several types of distal dystrophy are inherited as autosomal dominant traits. For example, Milhorat and Wolff studied 12 individuals from one family affected by “a progressive muscular dystrophy of atrophic distal type.” The onset was between 26 and 43 years; within 5 to 15 years the patients had become disabled. There was one autopsy, confirming the dystrophic nature of the disease.

A different dominantly inherited distal dystrophy was described by Welander in a study of 249 patients from 72 Swedish pedigrees (not to be confused with the Kugelberg-Welander juvenile spinal muscular atrophy affecting proximal muscles—see page 946). Weakness developed first in the small hand muscles and then spread to the distal leg muscles, causing a steppage gait. Fasciculations, cramps, pain, sensory disturbances, and myotonia were notably absent. Some patients have a low-grade sensory neuropathy, suggesting that pathology in this disorder may not be exclusively in muscle. Senile cataracts appeared after the age of 70 in 3 patients and can be discounted as having special significance. No endocrine disorders were detected. Dystrophic changes were demonstrated in 3 autopsies and 22 biopsy specimens. The central nervous system and peripheral nerves were normal. Progression of the disease was very slow; after 10 years or so some wasting of proximal muscles was seen in a few of the patients. Welander dystrophy has been linked to chromosome 2p13, near the locus for the below described Miyoshi myopathy.

Markesbery and colleagues reported a late-onset distal myopathy in which weakness began in the distal leg muscles (tibialis anterior) and later spread to the hands; there was also cardiomyopathy and heart failure. Identical distal myopathies have been described in Finnish patients by Udd and colleagues and found to be caused by dominant mutations in the “titin” gene. A form beginning in childhood described by Laing and colleagues was shown to be due to a mutation in the gene for myosin heavy chain. The characteristic feature in all these cases is progressive bilateral foot drop.

**Miyoshi Dystrophy** A second type of distal dystrophy characterized by autosomal recessive pattern of inheritance is particularly prevalent in Japan (Miyoshi et al, Nonaka et al), but numerous cases exist in all parts of the world. Onset of the disease is in early adult life, with weakness and atrophy of the leg muscles, most prominent in the peroneal or gastrocnemius and soleus muscles. Over many years the weakness extends to the thighs, gluteal muscles, and arm muscles, including the proximal ones. Serum CK concentrations are greatly increased in the early stages of the disease. In this “Miyoshi type” of dystrophy the mutation leads to an absence of the muscle protein dysferlin. Dysferlin is a membrane protein that does not interact with any of the dystrophin-binding elements. Whereas dystrophin and its binding partners are believed to confer tensile strength the muscle membrane, dysferlin and its associated proteins (e.g., the annexins) function in calcium-mediated membrane repair (Lennon). Of interest is the fact, mentioned earlier, that one of the limb-girdle dystrophies (2B) has been linked to the same chromosomal locus and also lacks the dysferlin protein. It is also striking that different family members with the same dysferlin mutation can have disease onset in either a proximal (LGMD) or distal (Miyoshi) pattern, suggesting that additional factors modify the pattern of weakness produced by dysferlin deficiency. We

IBM: inclusion body myopathy.

have encountered one family in which two individuals with dysferlin mutations had proximal weakness at onset while a sibling with the same lesion had anterior tibial weakness. The Miyoshi myopathy is the one we have encountered most often among the distal muscular dystrophies.

An apparently separate form of distal myopathy with autosomal dominant inheritance and onset before 2 years of age has been described by Magee and DeJong and by van der Does de Willebois and coworkers. Whether these infantile-onset cases represent a true muscular dystrophy has not been established beyond doubt. Several even rarer distal myopathies with linkage to specific genetic sites are summarized in the review by Illa but most are not well enough characterized to require elaboration here.

Congenital Muscular Dystrophy
(Fukuyama, Walker-Warburg, Merosin Deficient, Rigid Spine, and Other Types) (See Table 50-4)

Early in the twentieth century there were scattered reports of congenital myopathy, but the status of this condition was difficult to evaluate, mainly because of a lack of incompleteness of pathologic examinations. Some cases may have represented congenital myotonic dystrophy, or one of the congenital myopathies described in Chap. 52. In 1957 Banker, Victor, and Adams described two patients (siblings), one dying 1½ h after birth and the other at the age of 10 months of a congenital muscular dystrophy with arthrogryposis. The pathologic changes consisted of muscle fiber degeneration, variation in fiber size, fibrosis, and fat cell replacement. The central and peripheral nervous systems were intact. The severity of the degenerative changes was such that a developmental disorder of muscle could be excluded. Pearson and Fowler, in 1963, reported a brother and sister with similar clinical and pathologic findings, and Walton et al described yet another patient, aged 4 years. By 1967 Vassella and colleagues were able to collect 27 cases from the medical literature and to add 8 cases of their own. The high incidence of sibling involvement pointed to an autosomal recessive inheritance.

Defined as a muscle dystrophy already present at birth, often with contractures of proximal muscles and trunk, the severity of the weakness and degree of progression have varied widely. Of the 8 cases reported by Rotthauwe and others, one had a benign course, but the others all had weakness and hypotonia at birth, and difficulty in sucking and swallowing had interfered with nutrition. Their oldest patients, aged 14 and 23 years, and several others had walked, but at a late age. In the Finnish series of Donner and associates, congenital dystrophy accounted for 9 percent of the 160 cases of neuromuscular disease seen at their hospital over a decade. The weakness and hypotonia were generalized, and 3 had ECG abnormalities. The CK values were elevated and the EMGs were myopathic.

This group of dystrophies began to come into focus in the 1960s with a series of articles from Japan relating the details in over 100 patients with congenital dystrophy (Fukuyama et al). It is the second most common muscular dystrophy in Japan but it is rare elsewhere. A feature of these cases was the coexistence of severe mental retardation and developmental anomalies of the cerebral cortex. Hyperlucency in the periventricular white matter (by
computed tomography) was frequently observed. In another group of cases, congenital muscular dystrophy was associated with lissencephaly as well as cerebellar and retinal malformations (Walker-Warburg syndrome; see Dobyns et al.). In a series of 19 Finnish cases reported by Santavuori and coworkers, congenital muscular dystrophy was associated with retinal degeneration and optic atrophy, hydrocephalus, pachygyria-polymicrogyria, and hypoplastic or absent septum pellucidum and corpus callosum ("muscle-eye-brain" syndrome). Lebenthal and colleagues later described a large Arab pedigree with congenital muscular dystrophy and patent ductus arteriosus. Some patients had contractures at birth; in others contractures developed at a later age. The EMG disclosed a myopathic pattern, and CK levels were moderately elevated.

In recent years the classification and relationships of the congenital muscular dystrophies have been clarified to some extent by a number of molecular genetic studies (see Table 50-4). Remarkably, the major congenital muscular dystrophies share an important biological attribute: each involves either an abnormality of a protein that binds to the dystrophin complex (e.g., laminin α2 or merosin) or an abnormality of a protein in the Golgi apparatus that is important in processing proteins (such as the dystroglycans and sarcoglycans) that are destined to interact with the dystrophin complex (see Fig. 50-1).

The most frequent congenital muscular dystrophy in the Caucasian population is the classic (Occidental) type, so called because it is characterized exclusively by muscle involvement. Occasionally there are abnormal white matter signals on magnetic resonance imaging. Tomé and others have shown that in approximately one half such patients, merosin is completely absent ("merosin-negative" cases). Merosin, the predominant isoform of α-laminin in the basement membrane of the muscle fiber, is closely bound to α-dystroglycan, which in turn is bound to the dystrophin cytoskeleton (see Fig. 50-1). An absence of merosin interrupts this linkage and leads to muscle degeneration. The diagnosis of merosin deficiency can be made prenatally by immunostaining chorionic villi cells, and postnatally, by staining skeletal muscle biopsy material. In most cases that are merosin deficient, the disorder is genetically linked to the merosin (laminin α2) gene. These mutations would be predicted to alter or prevent the expression of the protein.

An additional member of the group of merosin-positive congenital muscular dystrophies is one termed *rigid spine syndrome*. The term was first proposed by Dubowitz and the clinical syndrome, as outlined by Flanigan and coworkers, consists of (1) infantile hypotonia with early weakness of neck muscles and poor head control; (2) stabilization with only slight decrease of muscle strength but marked loss of muscle bulk; (3) prominent contractures of spinal muscles resulting in scoliosis and rigidity in flexion and, to a lesser extent, contractures of limb joints; (4) respiratory insufficiency with onset before adolescence; and (5) normality of intellectual and cardiac function. This unusual congenital muscular dystrophy with rigid spine syndrome (CMD-RSS) arises from mutations in a gene encoding a so-called selenoprotein.

In the Fukuyama type of congenital muscular dystrophy, the abnormal gene product fukutin has been identified. As noted above, fukutin is one of five genes whose mutations alter protein glycosylation, deranging function of both muscle and brain. Thus, the genes for MEB and the Walker-Warburg syndrome are also glycosyltransferases (respectively, POMGnT1 and POMT1) as is the aforementioned fukutin-related peptide. Most recently, it has been shown that another form of congenital muscular dystrophy follows mutations of another glycosylation gene (known as "LARGE").

Problems in Diagnosis

The following are some of the common problems that arise in the diagnosis of muscular dystrophy:

1. The diagnosis of muscular dystrophy in a child who has just begun to walk or in whom walking is delayed. Tests of peak power on command cannot be used with reliability in small children. The most helpful points in identifying Duchenne dystrophy are (a) unusual difficulty in climbing stairs or arising from a crouch or from a recumbent position on the floor, showing greater weakness at the hips and knees than at the ankles; (b) unusually large, firm calves; (c) male sex; (d) high serum CK, aldolase, and myoglobin levels; (e) myopathic EMG; (f) biopsy findings; and (g) special methods of testing for dystrophin protein (see previous discussion).

2. The adult patient with diffuse or proximal muscle weakness of several months’ duration, raising the question of polymyositis versus dystrophy. Even biopsy may be misleading in showing a few inflammatory foci in an otherwise dystrophic picture. The main points that help to distinguish polymyositis from adult dystrophy have been indicated in Chap. 49. As a rule, polymyositis evolves more rapidly than dystrophy and is associated with high CK and aldolase values (higher than most of the dystrophies except the Duchenne and distal Miyoshi types), and the EMG shows many fibrillation potentials (rare in adult forms of muscular dystrophy). With these points in mind, if immunostaining of a muscle biopsy fails to reveal the diagnosis of a dystrophy, there may still be uncertainty, in which instance a trial of prednisone may be indicated for a period of 6 months. Unmistakable improvement favors polymyositis; questionable improvement (physician’s and patient’s judgment not in accord) leaves the diagnosis unsettled but suggests inclusion of body myopathy or a dystrophy.

3. An adult with a very slowly evolving proximal weakness. In addition to facioscapular and limb-girdle dystrophies, myositis and inclusion body myopathy, several of the congenital polymyopathies discussed in Chap. 52 may begin to cause symptoms or to worsen in adult years. These include central core and nemaline myopathy. Examples have been reported in the adult of mild forms of acid maltase or debrancher enzyme deficiency with glycogenesis, progressive late-stage hypokalemic polymyopathy, mitochondrial myopathy, and carnitine polymyopathy. Muscle biopsy and histochemical staining of the muscle usually provide the correct diagnosis.

4. The occurrence of subacute or chronic symmetrical proximal weakness in a child or adolescent that raises the question of spinal muscular atrophy (Kugelberg-Welander type—see page 946) as well as of polymyositis and muscular dystrophy. Electromyography and muscle biopsy settle the matter by distinguishing neuropathic from myopathic changes. Some of the same problems arise in an adult with distal dystrophy.

5. Weakness of a shoulder or one leg of some weeks’ standing, with increasing atrophy. This is usually due to a radiculopathy or mononeuropathy, the beginning of motor system disease (progressive spinal muscular atrophy), but rarely may be the early stage of a muscular dystrophy. The first two may develop silently, in mild form, and attract notice only when wasting begins (denervation atrophy takes 3 to 4 months to reach its peak). Points in favor of these acquired diseases are (a) acute or subacute onset and pain, (b) confinement of the disease to muscles originally affected and sparing of other muscles, and (c) an EMG showing denervation effects. Biopsy is seldom performed under such circumstances, for, by temporizing, the problem eventually settles itself. Invariably muscle dystrophy becomes bilateral and symmetrical; mononeuritis stabilizes or recovers; motor neuron disease declares itself by the presence of fasciculations and relatively rapid progression of weakness. Facioscapulohumeral dystrophy may begin with asymmetric shoulder weakness.

6. The distinctions, in the child or adolescent, between dystrophy and one of the congenital or metabolic myopathies are considered in relation to these disorders (Chaps. 51 and 52).

Treatment of the Muscular Dystrophies

There is no specific treatment for any of the muscular dystrophies. The physician is forced to stand by and witness the unrelenting progression of weakness and wasting. The various vitamins (including vitamin E), amino acids, testosterone, and drugs such as penicillamine, recommended in the past, have all proved to be ineffective. The administration of prednisone appears to slightly retard the tempo of progression of Duchenne dystrophy for a period of up to 3 years (Fenichel et al). The optimal dose is 0.75 mg/kg given daily, but it must often be reduced because of intolerable side effects (weight gain, behavioral and gastrointestinal disorders). Creatine may be of minor benefit as in the study by Walter and colleagues.

Quinine has a mild curare-like action at the motor end plate and thus relieves myotonia (see Chap. 54). Although symptomatic relief of the myotonia is usually achieved, the drug has no effect on progression of the muscle atrophy or other degenerative aspects of myotonic dystrophy. The usual dose is 0.3 to 0.6 g orally, repeated as needed about every 6 h. Mild toxic symptoms such as tinnitus may develop before enough quinine has been given to relieve myotonia. Some patients find the side effects more distressing than the myotonia and prefer not to take quinine except on occasions when the myotonia is troublesome in a particular activity. Also, procainamide (0.5 to 1.0 g 4 times daily) and phenytoin are sometimes useful in alleviating myotonia, but the former may be dangerous, even in patients with a pacemaker. (Quinine and procainamide slow conduction through the AV node, whereas phenytoin does not have this effect.) Testosterone has been found to increase muscle mass in patients with myotonic dystrophy but was of no value in preserving strength or lessening myotonia (Griggs et al).

Respiratory failure occurs in virtually all patients affected with Duchenne dystrophy after they become wheelchair-bound, as well as in some of the other dystrophic diseases. It may be so insidious as to become evident only as sleep apnea, as a retention of carbon dioxide that causes morning headache, or as progressive weight loss that reflects the excessive work of breathing. If there are frequent episodes of oxygen desaturation, some improvement in daytime strength and alertness can be attained by assisting ventilation at night. This may be accomplished in the early stages of disease by a negative-pressure cuirass-type of device that expands the chest wall periodically or, more conveniently, by nasal positive pressure (so-called NIPPV or BIPAP). Later, positive-pressure ventilation through a fenestrated tracheostomy is required that allows nighttime ventilation but leaves the patient free to speak and breathe.
during the day. With regard to earlier, or anticipatory treatment, in
patients free of respiratory failure with vital capacities between 20
and 50 percent of predicted values, a randomized trial of nasal
mechanical ventilation failed to demonstrate improvement or pro-
longed survival (Raphael et al). There is a clinical impression that
even more severely affected patients can be managed at home for
prolonged periods with respiratory assistance. Needless to say, the
common complications of muscular dystrophy—pulmonary infec-
tions and cardiac decompensation—must be treated symptomati-
cally. Surgical management of cataracts is indicated when they
become mature.

As noted earlier, a vital element in the care of patients with
certain of the dystrophies is monitoring for early evidence cardiac
arrhythmias. In disorders such as myotonic dystrophy, Emery-Drei-
fuss dystrophy, and some of the mitochondrial disorders it is im-
perative that cardiac status be evaluated on a regular basis
(typically yearly) with echocardiography and 24-h rhythm moni-
toring, preferably by a cardiologist who is familiar with these dis-
eases. The timely use of cardiac pacemakers, implemented at the
earliest sign of arrhythmia, is essential in this patient population.

Vignos, who reviewed the studies that evaluated muscle-
strengthening exercises, has offered evidence that maximal resis-
tance exercises, if begun early, can strengthen muscles in Duch-
enne, limb-girdle, and facioscapulohumeral dystrophies. In the
study he conducted, none of the muscles were weaker at the end
of a year than at the beginning. Cardiorespiratory function after
endurance exercise was not significantly improved. Contractures
were reduced by passive stretching of the muscles 20 to 30 times
a day and by splinting at night. If contractures have already formed,
fasciotomy and tendon lengthening are indicated in patients who
are still ambulating but this is not recommended early in the course
of the disease. Maintenance of ambulation and upright posture will
delay scoliosis. In general, preventive measures are more success-
ful than restorative ones.

In recent years there has been interest in the injection of hu-
man myoblasts or muscle stem cells that contain a full complement
of dystrophin and other structural elements into the muscles of
patients with muscular dystrophy. There is an analogous effort to
refine the technology of viral-mediated gene delivery to allow gene
and protein replacement in the recessively inherited dystrophies.
The difficulties of injecting every dystrophic muscle are obvious.
Thus far, there is no convincing evidence of the efficacy of such
injections, even for those into an individual muscle. Until such
time as gene or stem cell therapy, or other novel approaches, become
practical for muscular dystrophy, physicians must rely on physical
methods of rehabilitation.

From such observations it may be concluded that two factors
are of importance in the management of patients with muscular
dystrophy: avoiding prolonged bed rest and encouraging the patient
to maintain as full and normal a life as possible. These help to
prevent the rapid worsening associated with inactivity and to con-
serve a healthy attitude of mind. Obesity should be avoided; this
requires careful attention to diet. Swimming is a useful exercise.
Massage and electrical stimulation are probably worthless. The ed-
ucation of children with muscular dystrophy should continue, with
the aim of preparing them for a sedentary occupation.

Prevention by prenatal counseling is available for most dys-
trophies but proper diagnosis is essential. Special centers provide
the genetic and psychological services necessary to carry this out
properly.

CHAPTER 51

THE METABOLIC AND TOXIC MYOPATHIES

Three classes of metabolic disease of muscle are recognized—one of which is traceable to a primary, or hereditary, metabolic abnormality of the muscle itself; another in which the myopathy is secondary to a disorder of endocrine function, i.e., to disease of the thyroid, parathyroid, pituitary, or adrenal gland; and a third group, due to a large variety of myotoxic drugs and other chemical agents. The latter two groups are relatively common and more likely to come initially to the attention of the internist rather than the neurologist.

The hereditary metabolic myopathies are of special interest because they reveal certain aspects of the complex chemistry of muscle fibers. Indeed, each year brings to light some new genetically determined enzymopathy of muscle. As a consequence, a number of diseases formerly classified as dystrophic or degenerative, are consistently being added to the enlarging list of metabolic myopathies. There are now so many of them that only the most representative can be presented in a textbook of neuromuscular disease. Complete accounts of this subject can be found in the section on metabolic disorders in Engel and Franzini-Armstrong (eds.), Myology, and in the chapter by DiMauro and colleagues in the Handbook of Clinical Neurology.

PRIMARY METABOLIC DISORDERS OF MUSCLE

The chemical energy for muscle contraction is provided by the hydrolysis of adenosine triphosphate (ATP) to adenosine diphosphate (ADP); ATP is restored by phosphocreatine and ADP acting in combination. These reactions are particularly important during brief, high-intensity exercise. During periods of prolonged muscle activity, rephosphorylation requires the availability of carbohydrates, fatty acids, and ketones, which are catalyzed in mitochondria. Glycogen is the main sarcoplasmic source of carbohydrate, but blood glucose also moves freely in and out of muscle cells as needed during sustained exercise. The fatty acids in the blood, derived mainly from adipose tissue and intracellular lipid stores, constitute the other major source of energy. Carbohydrate is metabolized during aerobic and anaerobic phases of metabolism, the fatty acids, only aerobically.

Resting muscle derives approximately 70 percent of its energy from the oxidation of long-chain fatty acids. As stated earlier, the circumstances during exercise are somewhat different. During a short period of intense exercise, the muscle utilizes carbohydrate derived from glycogen stores; myophosphorylase is the enzyme that initiates the metabolism of glycogen. With longer aerobic exercise, blood flow to muscle and the availability of glucose and fatty acids is increased. At first, glucose is the main source of energy during exercise; later, with exhaustion of the glycogen stores, energy is provided by oxidation of fatty acids. Thus, muscle failure at a certain phase of exercise is predictive of the type of energy failure. A rising blood concentration of β-hydroxybutyrate reflects the increasing oxidation of fatty acids, and an increase in blood lactate reflects the anaerobic metabolism of glucose. The cytochrome oxidative mechanisms are essential in both aerobic and anaerobic muscle metabolism; these mechanisms are considered in Chap. 37 in relation to the mitochondrial diseases, and are referred to here only briefly.

It follows from these observations that the efficiency and endurance of muscle depend on a constant supply of glycogen, glucose, and fatty acids and on the adequacy of the enzymes committed to their metabolism. Biochemical derangements in their metabolism give rise to a large number of muscle disorders, the most important of which are elaborated in the following pages.

Glycogen Storage Myopathies

An abnormal accumulation of glycogen in the liver and kidneys was described by von Gierke in 1929; shortly thereafter, Pompe (1932) reported a similar disorder involving cardiac and skeletal muscle. Major contributions to our understanding of glycogen metabolism were made by McArdle, by Cori and Cori, and by Hers, who discovered the deficiency of acid maltase in Pompe disease and enunciated the concept of inborn lysosomal diseases (see Chap. 37). Since then, many nonlysosomal enzyme deficiencies have been identified and have become the basis of the classification presented in Table 51-1. These enzymatic deficiencies alter the metabolism of many cells but most strikingly those of the liver, heart, and skeletal muscle. In about half of the affected individuals, a chronically progressive or intermittent myopathic syndrome is the major manifestation of the disease. It is a curious fact, that with the exception of the rare phosphoglycerate kinase deficiency (X-linked recessive inheritance), all the glycogenoses are inherited as autosomal recessive traits. The most impressive and common of these glycogen storage diseases from the standpoint of the clinical neurologist are 1,4-glucosidase (acid maltase) and myophosphorylase deficiencies.

Acid Maltase Deficiency (Glycogenosis Type II; Pompe Disease and Related Disorders) A deficiency of this enzyme takes three clinical forms, of which the first (Pompe disease) is the most malignant. Pompe disease develops in infancy, between 2 and 6 months; dyspnea and cyanosis call attention to enlargement of the heart, and the liver may be enlarged as well. The skeletal muscles are found to be weak and hypotonic, though their bulk may be increased. The tongue may be enlarged, giving the infant a cretinoid appearance. Hepatomegaly, while often present, is not pronounced. Exceptionally, the heart is relatively normal in size, and the central nervous system and muscles bear the brunt of the disorder. The clinical picture then resembles infantile spinal muscular atrophy (Werdnig-Hoffmann disease) and, to add to difficulty in differential diagnosis, there may be fasciculations. The disease is rapidly progressive and ends fatally in a few months. The electromyogram (EMG) shows myopathic changes, but there are, in addition, fibrillation potentials, heightened insertional activity, and pseudomyotonia. Large amounts of glycogen accumulate in muscle, heart, liver, and neurons of the spinal cord and brain. All tissues lack alpha glucosidase (acid maltase). The gene encoding acid maltase;

has been mapped to the distal portion of the long arm of chromosome 17 (17q23).

In the second (childhood) form, onset is during the second year, with delay in walking and slowly progressive weakness of shoulder, pelvic girdle, and trunk muscles. The toe walking, waddling gait, enlargement of calf muscles, and lumbar lordosis resemble those of Duchenne dystrophy. Cardiomyopathy is exceptional, hepatomegaly is less frequent than in the infantile form, and mental retardation was present in only 2 of 18 cases reported by DiMauro et al. Death occurs between 3 and 24 years of age, usually from ventilatory insufficiency.

In the third, or adult, form there is a more benign truncal and proximal limb myopathy. The weakness is slowly progressive over many years, and death is usually the result of weakness of respiratory muscles. At times the only severe weakness is of the diaphragm, as in the case reported by Sivak and colleagues, making adult acid maltase deficiency part of a select group of neuromuscular disorders that may present in this way (along with motor neuron disease, nemaline rod myopathy, and myasthenia gravis). The liver and heart are not enlarged. Creatine kinase (CK) values are increased, as they are in all forms of the disease. The EMG discloses a number of abnormalities—brief motor unit potentials, fibrillation potentials, positive waves, bizarre high-frequency discharges, and occasional myotonic discharges (without clinical evidence of myotonia). The disease must be differentiated from other chronic adult polymyopathies, including polymyositis and the endocrine myopathies, and from motor neuron disease.

Aside from the elevation of the muscle-derived enzymes CK and aldolase, blood studies are normal. The diagnosis in all forms of acid maltase deficiency is readily confirmed by muscle biopsy. The sarcoplasm is vacuolated and most vacuoles contain periodic acid–Schiff (PAS)-positive diastase-digestible material; they stain intensely for acid phosphatase. The glycogen particles lie in aggregates; electron microscopy shows some of them to occupy lysosomal storage disease (without clinical evidence of myotonia). The disease must be differentiated from other chronic adult polymyopathies, including polymyositis and the endocrine myopathies, and from motor neuron disease.

The primary abnormality in McArdle disease is a deficiency of myophosphorylase, which prevents the conversion of glycogen to glucose-6-phosphate. Phosphofructokinase deficiency (Tarui disease) interferes with the conversion of glucose-6-phosphate to glucose-1-phosphate; the defect in the latter condition is also present in red blood cells (Layzer et al). The gene for myophosphorylase has been localized to the long arm of chromosome 11 (11q13), and analysis of DNA from the patient’s leukocytes can be used for diagnosis. The muscle (M) subunit of the phosphofructokinase protein in Tarui disease localizes to a gene defect on chromosome 1. This defect predominates in Ashkenazi Jewish men.

Clinical variants of these disorders are well known. Some patients, with no previous symptoms of cramps or myoglobinuria, develop progressive weakness of limb muscles in the sixth or seventh decade. One of these older patients came to our attention because of chronically elevated levels of CK and mild muscle cramping after climbing stairs. In others, rapidly progressive weakness became evident in infancy, with early death from respiratory failure. These unusual forms are not directly related to severity of the enzyme deficiencies.

The contracted muscles in these disorders, unlike muscles in other involuntary spasms, no longer use energy, and they are more or less electrically silent (i.e., no electrical activity is recorded from maximally contracted muscle during the cramps induced by ischemic exercise); moreover, the muscle does not produce lactic acid. This shortened state is spoken of as physiologic contracture. Ischemia contributes to this condition by denying glucose to the muscle, which cannot function adequately on fatty acids and non-glucose substrates. These features are the basis of the forearm ischemic exercise test, which, while controversial in its use, may be helpful if performed carefully in the diagnosis of both McArdle and Tarui disease. An indwelling catheter is placed in the antecubital vein and a basal blood sample is obtained. Above the elbow, a sphygmomanometer cuff is inflated to exceed arterial pressure. After 1 min of vigorous hand exercise (30 hand closures against an ergometer), blood samples are obtained at 1 and 3 min. Normal individuals show a three- to fivefold increase in blood lactate. In patients with either McArdle or Tarui disease, the lactate fails to rise. This procedure has reportedly caused a localized rhabdomyolysis (Meinck et al), for which reason Griggs and associates recommend that the test be carried out without a blood pressure cuff. Problems with consistency in conducting the test and processing blood samples for lactate limit its validity unless it is performed by experienced individuals and laboratories.

* All types: elevated CK; myopathic EMG, with increased irritability and myotonia.
* I, infancy; C, childhood; Ad, adolescence; A, adult.

Additional features (not charted above): feeding difficulties, II Pompe; retarded growth, III; neurologic abnormalities, II Pompe, IX; seizures, VIII, IX; hypoglycemic seizures, III; jaundice, VII, IX; cirrhosis, IV; generalized scaling erythema, XI; firm consistency of muscle, II Pompe; elevated serum aspartate aminotransferase and lactic dehydrogenase, II; elevated serum bilirubin, VII, IX; failure of LDH to rise proportionally to elevation of CK, XI; fasting hypoglycemia, III; hemolytic anemia and reticulocytosis, VII, IX; hemoglobinuria, IX; excessive rise in serum pyruvates during ischemic exercise test, XI.

Definitive diagnosis depends upon the histochemical stains of biopsied muscle, which reveal an absence of phosphorylase activity (in McArdle disease) or of phosphofructokinase activity (in Tarui disease).

**Treatment**  The main treatment is a planned reduction and intermittency in physical activity. Sucrose, taken as 75 g in a beverage, has been shown by Vissing and Haller to cause a short-lived improvement in exercises tolerance and they propose that exercise-induced rhabdomyolysis can be avoided by this well-timed drink. Fructose and creatine taken orally are also said to be helpful in some cases but the reported results are not as impressive as they are for sucrose. Improvement has also been described after the administration of glucagon (Kono et al) and after a high-protein diet (Slonim and Goans), but these effects are not consistent.

**Other Forms of Glycogenosis** (see Table 51-1)  Of the remaining glycogen storage diseases, type III (debranching enzyme deficiency; Cori-Forbes disease) affects muscle, but not consistently. The childhood form is characterized mainly by a benign hepatopathy, sometimes accompanied by diminished muscle strength and tone. An adult form beginning in the third and fourth decades presents with proximal and distal myopathy. The course is slowly progressive and may be associated with wasting of the leg and hand muscles. In the series reported by DiMauro and colleagues, several patients who developed weakness during adult life complained of rapid fatigue and aching of muscles, occurring with exertion and first noticed at an early age. Serum CK values were elevated and the EMG showed a myopathic picture as well as increased insertional activity, pseudomyotonic discharges, and fibrillation potentials. Rarely in the adult form, glycogen also accumulates in the
peripheral nerves, giving rise to mild symptoms of polyneuropathy. The enzymatic defect is one of amylo-1,6-glucosidase deficiency.

Disturbance of skeletal muscle is even less prominent in type IV glycogenosis (branching enzyme deficiency, or Andersen disease). This is a rapidly progressive disease of infancy and early childhood, characterized by cirrhosis and chronic hepatic failure, usually with death in the second or third year. Hepatomegaly due to accumulation of an abnormal polysaccharide is a universal finding. Muscle weakness and atrophy, hypotonia, and contractures occur less regularly and are usually overshadowed by the liver disease. The diagnostic hallmark of this myopathy is the presence of basophilic, intensely PAS-positive polysaccharide granules in skin and muscle.

The remaining nonlysosomal glycogenoses (types VIII through XI) need only be mentioned briefly. They are all rare and clinically heterogeneous, and a myopathy—characterized by intolerance to exercise, cramps, myoglobinuria, elevated CK, and sometimes renal failure—has been observed in only a small proportion of them. Phosphoglycerate kinase deficiency (type IX glycogenosis) differs in that it is inherited as a sex-linked recessive trait localized to chromosome Xq13. Hemolytic anemia—becoming evident soon after birth—mental retardation, seizures, and tremor are other features that set this glycogenosis apart from the others. The myopathic features of the lysosomal and nonlysosomal glycogenoses are listed in Table 51-1 and detailed accounts can be found in the monographs of Griggs and associates and of Engel and Franzini-Armstrong (chapters by DiMauro and Tsujino and by Engel and Hirschhorn).

Disorders of Lipid Metabolism Affecting Muscle

Although it has long been known that lipids are an important source of energy in muscle metabolism (along with glucose), it was only in 1970 that W. K. Engel and others reported the abnormal storage of lipid in muscle fibers attributable to a defect in the oxidation of long-chain fatty acids. The subjects of their report were twin sisters who had experienced intermittent cramping of muscles associated with myoglobinuria after vigorous exercise. In 1973, A. G. Engel and Angelini described a young woman with progressive myopathy, lipid storage predominantly in type 1 muscle fibers, and a deficiency of muscle carnitine, a cofactor
required for the oxidation of fatty acids. Since that time, highly sophisticated biochemical techniques have greatly expanded the study of fatty acid metabolism and the identification of many of the primary defects.

Biochemistry of Fatty Acid Metabolism Carnitine (β-hydroxy-gamma-N-trimethylamino-butyrate), derived from lysine and methionine, plays a central role in the metabolism of fatty acids. About 75 percent of carnitine comes from dietary sources (red meat and dairy products); the remainder is synthesized in the liver and kidneys. Practically all of the body carnitine is stored in muscle, where it has two main functions: (1) transporting long-chain fatty acyl-CoAs from the cytosol compartment of the muscle fiber into the mitochondria, where they undergo β-oxidation, and (2) preventing the intramitochondrial accumulation of acyl-CoAs, thus protecting the muscle cell from the membrane-destabilizing effects of these substances.

In order to be oxidized, the long-chain fatty acids undergo a series of biochemical transformations. First they are activated to corresponding acyl-CoA esters by acyl-CoA synthetase, which is located on the outer mitochondrial membrane. Since the inner mitochondrial membrane is impermeable to acyl-CoA esters, they are transferred into the mitochondria as acylcarnitine esters. This is accomplished by carnitine palmitoyl transferase I (CPT I), also located on the outer mitochondrial membrane. A second carnitine palmitoyl transferase (CPT II), bound to the inner face of the inner mitochondrial membrane, reconverts the acylcarnitines to fatty acyl-CoAs, which undergo β-oxidation within the mitochondrial matrix. The steps in the transport of long-chain fatty acids into the mitochondrial matrix (the carnitine cycle) are described in detail in the reviews of DiMauro et al, DiDonato, and Roe and Coates. Isoforms of carnitine palmitoyltransferase are critically involved in this process at the inner and outer membranes of the mitochondria.

Clinical Features of Disordered Fatty Acid Metabolism Despite the many biochemical abnormalities that have been identified in the fatty acid metabolic pathways, there are essentially three clinical patterns by which these defects are expressed:

1. One constellation of symptoms referred to as the encephalopathy syndrome has its onset in infancy or early childhood. Its very first manifestation may be sudden death (sudden infant death syndrome, or SIDS), or there may be vomiting, lethargy and coma, hepatomegaly, cardiomegaly, muscular weakness, and hypoketotic hypoglycemia, with prominent hyperammonemia, i.e., a Reye-like syndrome. Undoubtedly, instances of this syndrome have not been recognized as abnormalities of fatty acid metabolism but have been designated incorrectly as the Reye syndrome or as SIDS. They are discussed in Chap. 37.

2. A second (myopathic) syndrome appears in late infancy, childhood, or adult life and takes the form of a progressive myopathy, with or without cardiomyopathy. The myopathy may follow episodes of hypoketotic hypoglycemia or may develop de novo.

3. The third syndrome is one that usually begins in the second decade of life. It is induced by a sustained period of physical activity or fasting and is characterized by repeated episodes of rhabdomyolysis with or without myoglobinuria.

Summarized below are the main disorders of fatty acid metabolism that affect skeletal muscle; these are all rare but interesting disorders:

Primary Systemic Carnitine Deficiency To date, this is the only form of carnitine deficiency that can be considered primary. Its main clinical features are progressive lipid storage myopathy and cardiomyopathy, sometimes associated with the signs of hypoketotic hypoglycemia. There is no dicarboxylic aciduria, in distinction to the secondary β-oxidation defects, in all of which dicarboxylic aciduria is present. The cardiomyopathy, which is fatal if untreated, responds dramatically to oral administration of L-carnitine, 2 to 6 g/day. This disorder is inherited as an autosomal recessive trait. In these families there is frequently a history of sudden unexplained death in siblings, so that early identification of affected children is essential.

Carnitine Palmitoyltransferase (CPT) Deficiency This disease is also inherited as an autosomal recessive trait. The gene encoding CPT has been mapped to chromosome 1q12. There are three types of CPT deficiency, referred to as types I, IIA, and IIB. Type I is the most common. It affects males predominantly, beginning in the second decade of life. Attacks of myalgia, cramps, and muscle weakness, “tightness,” and stiffness are precipitated by sustained (though not necessarily intense) exercise and less often by a prolonged period of fasting. Fever, anesthesias, drugs, emotional stress, and cold are rare precipitating events. The attacks vary greatly in frequency. They are usually accompanied by myoglobinuria, and renal failure occurs in about one fourth of cases (DiMauro et al). The attacks are not aborted by rest and, once initiated, there is no second-wind phenomenon. There are no warning signs of an impending attack. Any muscle group may be affected. Persistence of weakness after an attack is uncommon. Serum CK rises to high levels not only during attacks of myoglobinuria but also after vigorous exercise without myoglobinuria. A mild form is more likely to occur in females.

In type I deficiency, necrosis of muscle fibers, particularly type I fibers, occurs during attacks, followed by regeneration. Between attacks, muscle is normal. In type IIA, lipid bodies accumulate in the liver, and in type IIB, excess lipid is detected in heart, liver, kidneys, and skeletal muscle.

During attacks, CPT is either undetectable or greatly reduced in muscle. Dicarboxylic aciduria is absent. Assays are available for the measurement of CPT I and II in circulating lymphocytes and cultured fibroblasts.

Treatment There is no specific therapy except that directed at the myoglobinuria and its renal complications. However, a high-carbohydrate, low-fat diet, ingestion of frequent meals, and additional carbohydrate before and during exercise appear to reduce the number of attacks. Patients need to be instructed about the risks of prolonged exercise and skipped meals.

Secondary Systemic Carnitine Deficiency This is occasionally the result of severe dietary deprivation or impaired hepatic and renal function. Such instances have been observed in patients with alcoholic-nutritional diseases and kwashiorkor, in premature infants receiving parenteral nutrition, in patients with chronic renal failure undergoing dialysis, and rarely as a complication of valproate therapy. However, most cases of systemic carnitine deficiency are due to defects of β-oxidation, described below.
Other Rare Lipid Myopathies

Defects of β-Oxidation  Rarely do these defects affect muscle alone or predominantly. Practically always, other features of disordered fatty acid metabolism—liver disease, hypoketotic hypoglycemia, Reye-like syndrome, SIDS, and so on—are present in some combination. All of the β-oxidative defects are characterized by dicarboxylic aciduria. The abnormal organic acids in each case are determined by analysis of blood and urine; identification of the specific enzyme deficiency requires tissue analysis (liver and muscle homogenates, cultured fibroblasts). At the time of this writing, no less than eight specific defects of β-oxidation affecting muscle have been described; they are tabulated below.

Carnitine Acylcarnitine Translocase Deficiency  This condition causes muscular weakness, cardiomyopathy, hypoketotic hypoglycemia, and hyperammonemia, which develop in early infancy, with death in the first month of life.

Long-Chain Acyl-CoA Dehydrogenase Deficiency (LCAD)  The presentation is in infancy, with recurrent episodes of fasting hypoglycemic coma, muscle weakness, and myoglobinuria, and sometimes sudden death. Survivors may develop a progressive myopathy. Administration of carnitine improves the cardiac disorder and prevents metabolic attacks.

Medium-Chain Acyl-CoA Dehydrogenase Deficiency (MCAD)  This is a cause of SIDS and a Reye-like syndrome. About half of survivors develop a lipid-storage myopathy in childhood or adult life. The abnormal gene has been mapped to chromosome 1p31. Oral L-carnitine may be of therapeutic value.

Short-Chain Acyl-CoA Dehydrogenase Deficiency (SCAD)  This myopathy in a limb-girdle distribution may appear initially in older children and adults, or it may follow episodic metabolic disorders in infancy.

Long-Chain Hydroxyacyl-CoA Dehydrogenase Deficiency (HAD)  This is a disease of infancy marked by episodes of Reye-like syndrome, hypoketotic hypoglycemia, lipid storage myopathy, cardiomyopathy, and sometimes sudden death.

Short-Chain Hydroxyacyl-CoA Dehydrogenase Deficiency (SCHAD)  This presents as an episodic disorder such as the one described earlier (HAD), but its onset occurs in adolescence. Recurrent attacks may be associated with myoglobinuria.

Multiple Acyl-CoA Dehydrogenase Deficiency (MADD); Glutaric Aciduria Type II (GA II)  Some cases are caused by a deficiency of electron transfer flavoprotein (ETF) and others by a deficiency of electron transfer flavoprotein-coenzyme Q oxidoreductase (ETF-QO). In the severest form of MADD, infants are born prematurely and many die within the first week of life; added to the common metabolic abnormalities are multiple congenital defects and a characteristic “sweaty feet” odor. In less severe cases, the congenital anomalies are absent. In the least severe form, the onset may be in late infancy (with episodic metabolic disturbances) or in childhood or adult life (with a lipid storage myopathy and a deficiency of serum and muscle carnitine). The prenatal diagnosis of GA II is suggested by the finding of large amounts of glutaric acid in the amniotic fluid. In the milder forms of the disease, oral riboflavin (100 to 300 mg/day) may be helpful.

Muscle Coenzyme Q10 Deficiency  This condition presents as a slowly progressive lipid storage myopathy from early childhood. The basic defect is in coenzyme Q10 in the respiratory chain of muscle mitochondria. The administration of coenzyme 10 has improved the myopathy.

Multisystem Triglyceride Storage Disease (Chanarin Disease)  This abnormality of lipid metabolism is distinct from the β-oxidation defects. A progressive myopathy is combined with ichthyosis and neurologic manifestations, such as developmental delay, ataxia, neurosensory hearing loss, and microcephaly. The lipid material is stored in muscle as triglyceride droplets that are nonlysosomal and non-membrane-bound.

Mitochondrial Myopathies

The genetic aspects of mitochondrial diseases and the diverse and overlapping clinical syndromes that constitute this category—including the myopathic ones—are discussed in Chap. 37. The histologic change termed ragged red fibers reflect the mitochondrial changes of this class of diseases and is common to many of them, even without manifest symptoms of muscle disease.

The Endocrine Myopathies

Thyroid Myopathies

Several myopathic diseases are related to alterations in thyroid function: (1) chronic thyrotoxic myopathy, (2) exophthalmic ophthalmoplegia (infiltrative ophthalmoplegia), (3) myasthenia gravis associated with thyrotoxicosis; (4) periodic paralysis associated with thyrotoxicosis, and (5) muscle hypertrophy and slow muscle contraction and relaxation associated with myxedema and cretinism. Although they are not common, we have encountered several examples of these diseases in a single year in our general hospitals.

Chronic Thyrotoxic Myopathy  This disorder, first noted by Graves and Basedow in the early nineteenth century, is characterized by progressive weakness and wasting of the skeletal musculature, occurring in conjunction with overt or covert (“masked”) hyperthyroidism. The thyroid disease is usually chronic and the goiter is of the nodular rather than the diffuse type. Exophthalmos and other classic signs of hyperthyroidism are often present but need not be. This complication of hyperthyroidism is most frequent in middle age, and men are more susceptible than women. Some degree of myopathy has been found in more than 50 percent of thyrotoxic patients. The onset is insidious and the weakness progresses over weeks and months. The muscular disorder is most often mild to moderate in degree, but it may be so severe as to suggest progressive spinal muscular atrophy (motor system disease). Muscles of the pelvic girdle and thighs are weakened more than others (Basedow paraplegia), though all are affected to some extent, even the bulbar muscles and rarely the ocular ones. However, the shoulder and hand muscles show the most conspicuous atrophy (not an obligatory feature). Tremor and twitching during contraction may occur, but we have not seen fasciculations. The tendon reflexes are of average briskness, possibly more lively than normal. Both the contraction and relaxation phases of the tendon reflexes are shortened, but usually this cannot be detected by the clinician. Serum concentrations of muscle enzymes are not increased and may be reduced. Usually the EMG is normal, without fibrillation potentials, though occasionally the action potentials are abnormally brief or polyphasic. Biopsies of muscle, except for slight atrophy of both type 1 and 2 fibers and an occasional degenerating fiber, have been normal. Administration of neostigmine has no effect. Muscle power and bulk are gradually restored when thy-roid activity is reduced to normal levels.
Exophthalmic Ophthalmoplegia (Graves Ophthalmopathy)

(See also page 235) These terms refer to the co-occurrence of weakness of the ocular muscles and exophthalmos in patients with Graves disease (pupillary and ciliary muscles are always spared). The exophthalmos varies in degree, sometimes being absent at an early stage of the disease, and is not in itself responsible for the muscle weakness. Often there is orbital pain. Both the exophthalmos and the weakness of the extraocular muscles may precede the signs of hyperthyroidism, associated with the other classic features of hyperthyroidism (tachycardia, weight loss, tremor), or may follow effective treatment of the disorder. The eye signs become apparent over days or weeks. The extraocular muscle palsies or exophthalmos may occasionally be unilateral, especially at the onset of the illness. Any of the external eye muscles may be affected, usually one more than others, accounting for strabismus and diplopia; the inferior and medial recti are the most frequently affected, but upward movements are usually limited as well. The typical but not invariable sign of lid retraction imparts a staring appearance. Subtle exophthalmos can be appreciated by standing above and behind the seated patient and observing the relative positions of the lids and the eyelashes. Conjunctival edema and vascular engorgement over the insertions of the medial and lateral rectus muscles can be appreciated by inspecting the globe in its extreme lateral positions. In advanced cases, the enlarged muscle insertions themselves can be detected by inspection and palpation. These swollen muscles are visible on orbital ultrasound, computed tomography, and magnetic resonance imaging.

Examination of the eye muscles in biopsy and autopsy material has shown prominent fibroblasts, many degenerated fibers, and infiltrations of lymphocytes, mononuclear leukocytes, and lipocytes; hence the term infiltrative ophthalmopathy. These histopathologic findings are suggestive of an autoimmune disease—a hypothesis supported by the finding of serum antibodies that react with extracts of eye muscles (Kodama et al). Possibly the antibodies target glycosaminoglycans of the orbital fibroblasts. β-adrenergic sensitivity of muscle fibers caused by excessive thyroid hormone has also been postulated. Other factors may be involved, such as the small size of oculomotor motor units, the absence of dystrophin, and the rich mitochondrial content. The condition often runs as the small size of oculomotor motor units, the absence of dystrophin, and the rich mitochondrial content. The condition often runs, consisting of diffuse myalgia and increased volume, stiffness, and slowness of contraction and relaxation—are common manifestations of hypothyroidism, whether in the form of myxedema or cretinism. These changes probably account for the relatively large tongue and dysarthria that one observes in myxedema. Weakness, however, is not a prominent feature. The presence of action myospasm and myokymia (both of which are rare) and of percussion myoedema and slowness of both the contraction and relaxation phases of tendon reflexes assists the examiner in making a bedside diagnosis. Cretinism in association with these muscle abnormalities is known as the Kocher-Debré-Semelaigne syndrome, and myxedema in childhood or adult life with muscle hypertrophy is known as the Hoffmann syndrome; the latter simulates hypothyrophia muscularis vera and myotonia congenita. In neither cretinism nor myxedema, however, is there evidence of true myotonia, either by clinical test or by EMG, although muscle action potentials are myopathic and often show bizarre high-frequency discharges. Serum transaminase values are normal, but CK levels are usually elevated, often markedly so. Serum globulin may also be increased. Muscle biopsies have disclosed only the presence of large fibers or an increase in the proportion of small fibers (either type 1 or 2) and slight distention of the sarcoplasmic reticulum and subsarcolemmal glycogen (probably all due to disuse atrophy).
The administration of thyroxine corrects the muscle disturbance.

Pathogenesis of the Thyroid Myopathies  How thyroid hormone affects the muscle fiber is still a matter of conjecture. Clinical data indicate that thyroxine influences the contractile process in some manner but does not interfere with the transmission of impulses in the peripheral nerve across the myoneural junction or along the sarcolemma. In hyperthyroidism this functional disorder enhances the speed of the contractile process and reduces its duration, the net effect being fatigability, weakness, and loss of endurance of muscle action. In hypothyroidism, muscle contraction is slowed, as is relaxation, and its duration is prolonged.

The speed of the contractile process is related to the quantity of myosin adenosinetriphosphatase (ATPase), which is increased in hyperthyroid muscle and decreased in hypothyroid muscle. The speed of relaxation depends on the rate of release and reaccumulation of calcium in the endoplasmic reticulum. This is slowed in hypothyroidism and increased in hyperthyroidism (Ianuzzo et al). The myopathic effects of hypothyroidism need to be distinguished from those of a neuropathy, which may rarely complicate hypothyroidism (page 1151).

Corticosteroid Myopathies

The widespread use of adrenal corticosteroids has created a class of muscle diseases similar to the one that occurs in the Cushing syndrome (Müller and Kugelberg). A deficiency of corticosteroids, as occurs in Addison disease, also causes generalized weakness, but without an identifiable muscle disease.

Corticosteroid and Cushing Disease Myopathy  The prolonged use of corticosteroids causes the proximal limb and girdle musculature to become weak, to the point where the patient may have difficulty in elevating the arms and arising from a sitting, squatting, or kneeling position; walking, particularly up stairs, may also be hampered. Some individuals seem to be more susceptible than others. The problem often arises of distinguishing an iatrogenic steroid-induced myopathy from the weakness produced by a primary neuromuscular disease that is being treated with these medications. The EMG is either normal or mildly myopathic, with small and abundant action potentials but no fibrillations. Biopsies disclose only a slight variation in fiber size, with atrophic fibers, mainly of type 2b, but little or no fiber necrosis and no inflammatory cells. Electron microscopically, there are aggregates of mitochondria, accumulations of glycogen and lipid, and slight myofibrillar loss (disuse atrophy). The serum CK and aldolase are usually normal. These changes are the same as those that characterize Cushing disease and may suggest that diagnosis (page 488).

There is only a poor correlation between the total dose of corticosteroid and the severity of muscle weakness. Nevertheless, in patients who develop this type of myopathy, the corticosteroid dosage has usually been high and sustained over a period of months or years. All corticosteroids may produce the disorder, although fluorinated ones are said to be more culpable than others. Discontinuation or reduction of corticosteroid administration leads to gradual improvement and recovery; alternate day regimens may also be helpful.

The mechanism by which corticosteroids cause muscle weakness is not known. In corticosteroid-treated animals, there is a measurable decrease in the uptake of amino acids and protein synthesis by muscle cells.

Acute Steroid Myopathy (Critical Illness Myopathy; Acute Quadriplegic Myopathy)  In addition to the well-known proximal myopathy induced by the long-term use of steroids, an acute and severe myopathy has been recognized in critically ill patients. It was described initially in patients with severe asthma who were exposed to high doses of steroids. Subsequently this acute myopathy has been recognized with numerous critical systemic diseases and organ failures, again, in the context of treatment with high doses of corticosteroids and, in a few cases, with sepsis and shock alone. The use of neuromuscular blocking agents appears to play an important complementary role in the genesis of the myopathy, being a factor in over 80 percent of reported cases, but it is uncertain whether these agents alone can produce a similar process (see reviews by Gorson and Ropper, Lacomis et al, and Barohn et al).

Patients who acquire this problem have generally been exposed to high doses of corticosteroids, sometimes for only brief periods. Exceptional instances have been reported in which the myopathy was induced by doses as low as 60 mg prednisone administered for 5 days, but we have not encountered such a case. The degree and type of simultaneous exposure to neuromuscular blocking agents has varied, but the doses have generally been quite high, falling in the range of a total dose of 500 to 4000 mg of pancuronium or its equivalent over several days.

The severe muscle weakness usually becomes evident when the systemic illness subsides, as attempts are made to wean the patient from the ventilator. The tendon reflexes are normal or diminished and there may be confounding features of a polyneuropathy, which is also known to be induced by critical illness and sepsis (page 1128). Most of our patients with acute myopathy have recovered over a period of many weeks after the corticosteroid agent has been withdrawn, but a few have remained weak for as long as a year.

Serum CK is elevated, at least early in the process. The EMG discloses the characteristic features of a myopathy; often there are fibrillations as well, theorized to be due to separation of the motor end-plate region from intact segments of muscle fibers. Polynuropathy and residual effects of neuromuscular blockade can be excluded by appropriate electrophysiologic studies. Muscle biopsy shows varying degrees of necrosis and vacuolation affecting mainly type 2 fibers. The most characteristic feature is a striking loss of thick (myosin) filaments. Severe degrees of muscle necrosis have been accompanied by massively elevated CK levels and by myoglobinuria and renal failure.

Several experimental observations may explain the apparent additive effect on muscle of corticosteroids and neuromuscular blocking agents. Animals exposed to high doses of steroids soon after muscle denervation display a selective loss of myosin, the characteristic finding of acute steroid myopathy. This depletion of myosin is reversed by reinnervation but not by withdrawal of the corticosteroids. Furthermore, denervation of muscle has been found to induce an increase in glucocorticoid receptors on the surface of the muscle. Dubois and Almon have postulated that exposure to neuromuscular blocking agents creates a functional denervation, rendering the muscle fiber vulnerable to the damaging effects of steroids. It is curious that this myopathy has not been seen after high-dose corticosteroid administration for neurologic diseases such as multiple sclerosis, but the observation of Panegyres and colleagues of a patient with myasthenia who developed a severe,
myosin-depleted myopathy following high doses of methylprednisolone supports such a dual action of denervation (at the postsynaptic membrane) and glucocorticoids.

Adrenocortical Insufficiency

Generalized weakness and fatigability are characteristic of adrenocortical insufficiency, whether primary in type, i.e., due to Addison disease (infectious, neoplastic, or autoimmune destruction of the adrenal glands or adrenal hemorrhage), or secondary to a pituitary deficiency of adrenocorticotropic hormone (ACTH). The weakness and fatigability, however, are related to mostly water and electrolyte disturbances and hypotension, not to a primary disorder of muscle. Biopsy has not disclosed any abnormalities of muscle, and postmortem examination of the muscle in one case showed no changes. Likewise, the EMG is normal, and the tendon reflexes are retained. Addisonian weakness responds (as does hyperkalemic paralysis) to glucocorticoid and mineralocorticoid replacement.

Primary Aldosteronism  Production of an excess of aldosterone by adrenal adenomas has been the subject of many articles, one of the earliest and most notable being that of Conn. Muscular weakness has been observed in three-quarters of the reported cases, and in nearly half of them there was either hypokalemic periodic paralysis or tetany. Chronic potassium deficiency may express itself either by periodic weakness or by a chronic myopathic weakness. An associated severe alkalosis causes the tetany. As in the weakness of Addison disease, there is no structural disorder of muscle except perhaps for vacuolation, which is the result of severe hypokalemia.

Diseases of Parathyroid Glands and Vitamin D Deficiency

A small proportion of patients with parathyroid adenomas complain of weakness and fatigability. Vicale described the first example of this disorder and remarked on the muscular atrophy and weakness and the pain on passive or active movement. The tendon reflexes were retained. A few scattered muscle fibers had undergone degeneration. Claims for a denervative process are disputed. We have not been impressed with either a myopathy or neuropathy in this disease.

In hypoparathyroidism, muscle cramping is prominent but there are no other neuromuscular manifestations. In both hypoparathyroidism and pseudohypoparathyroidism—the latter with characteristic skeletal abnormalities and, in some instances, mental slowness—the most important muscle abnormality is tetany. This is due to low ionized serum calcium, which depolarizes axons more than muscle fibers (see pages 1096 and 1276).

Osteomalacia, due to vitamin D deficiency and disorders of renal tubular absorption, often includes muscle weakness and pain as common complaints, similar to those in patients with primary hyperparathyroidism and uremia (see Layzer for further comment).

More striking than any of the foregoing disturbances, in our view, has been a chronic proximal myopathy in conjunction with hypophosphatemia associated with solitary bone cysts. In two of our patients, removal of the cyst restored serum phosphorus levels and cured the generalized muscle weakness. Also known is an uncommon syndrome of severe hypophosphatemia and generalized bone pain in association with usually benign mesenchymal tumors of soft tissue and bone (oncogenic hypophosphatemia). These tumors express a type of fibroblast growth factor that induces renal wasting of phosphorous. Hypophosphatemic myopathic weakness has been noted in our critical care unit, often precipitated by hyperalimentation solutions; the onset of weakness can be so abrupt as to simulate the Guillain-Barré syndrome. The oral administration of phosphates to raise the serum phosphorus cures the nonneoplastic cases. Some cases are accompanied by pain and stiffness. Presumably the phosphorus depletion in these disorders limits the phosphorylation reactions and the synthesis of ATP in muscle.

Diseases of the Pituitary Gland

Proximal muscle weakness and atrophy have been recorded as late developments in many acromegalic patients. Formerly thought to be due to neuropathy, these symptoms in acromegaly have been convincingly shown by Mastaglia and colleagues to be the result of a chronic polymyopathy. The serum CK is slightly elevated in some cases, and myopathic potentials are observed in the EMG. Biopsy specimens have shown atrophy and reduced numbers of type 2 fibers but necrosis of only a few fibers. Treatment of the pituitary adenoma and correction of the hormonal changes restores strength. A mild peripheral neuropathy of sensorimotor type has also been reported in a few patients with acromegaly but is less frequent than carpal tunnel syndrome in this disease.

**MYOPATHIES DUE TO DRUGS AND TOXINS**

A vast number of drugs and other chemical agents have been identified as myotoxic. Curry and colleagues, in 1989, found reports (in the English literature alone) of about 100 drugs that had caused rhabdomyolysis and myoglobinuria, mostly in an idiosyncratic manner. The list continues to grow, and additional myotoxic agents can be expected to appear as new drugs are introduced. It is not practical to describe all the myotoxins individually; they are, therefore, broadly categorized and their main features listed in Table 51-2.

Toxic agents produce myopathic changes in several ways. They may act directly on muscle cells, either diffusely or locally, as occurs with intramuscular injections, or the muscle damage can be due to diverse secondary factors—electrolyte disturbances (hypokalemia), renal failure, excessive energy requirements of muscle (as occur with drug-induced seizures and malignant hyperthermia), or inadequate delivery of oxygen and nutrients (drug-induced coma with compressive-ischemic injury of muscle). The most important category is that of direct toxic effect on the muscle membrane on the internal apparatus of the cell.

Several clinical features mark a myopathy as toxic in nature: lack of pre-existing muscular symptoms; predictable delay in onset of symptoms after exposure to a putative toxin; lack of any other cause for the myopathy; and often complete or partial resolution of symptoms after withdrawal of the toxic agent. Pathologically, this group of disorders is characterized by nonspecific myopathic changes, which in most severe degrees take the form of myonecrosis (rhabdomyolysis) and myoglobinuria. This necrotizing muscle syndrome is the most frequent and serious myotoxic syndrome and is discussed later, along with its more important causes.

Necrotizing Polymyopathy (Rhabdomyolysis) with Myoglobinuria  In any disease that results in rapid destruction of striated
massive rhabdomyolysis, and, correspondingly, there is a very high globin (although this does occur). It is more likely to result from the mechanism of the renal damage is not entirely clear; probably it is not albuminuria. When myoglobinuria is severe, renal damage may recovery occurs within a few days and there is only a residual and sometimes of the trunk) are swollen and congested. There may be tissues overlying the affected muscles (nearly always of the limbs muscles become painful and tender within a few hours. Power of acute alcoholic intoxication and malignant hyperthermia. The for- nation always suggests an underlying metabolic disease of muscle; conga drumming, or simply excessive exercise—although the lat-

Muscle fibers (rhabdomyolysis), myoglobin and other muscle pro-
teins may enter the bloodstream and appear in the urine. The latter is “cola”-colored (burgundy red or brown), much like the urine in hemoglobinuria. In hemoglobinuria, however, the serum is initially pink, because hemoglobin (but not myoglobin) is bound to haptoglobin, and this complex is not excreted in the urine as readily as myoglobin; also, the hemoglobin molecule is three times as large as the myoglobin molecule. (The hemoglobin-haptoglobin complex is removed from the blood plasma over a period of hours and haptoglobin may be depleted, so that hemoglobinuria is present without grossly evident hemoglobinemia.) Differentiation of the two pigments in urine is difficult; both are guaiac-positive and may be detected by a “dipstick,” a test that can be used to advantage at the bedside in appropriate circumstances. Only small differences are seen on spectroscopic examination. The most sensitive means of detecting myoglobin is by radioimmunoassay. It should be men-
tioned that porphyrins are another cause of discoloration of the urine. The clinical picture in porphyria is one of a polyneuropathy and not a myopathy.

Many of the causes of myonecrosis and myoglobinuria have already been mentioned above and in previous chapters. Myo-
globinuria may be detected in cases of acute inflammatory myopathy, in several types of glycogenosis (see Table 51-1), in car-
nitine palmitoyltransferase deficiency, and as a result of poisoning or therapeutic use of a vast array of drugs (including the combi-
nation of steroids and pancuronium, discussed earlier), toxins, and venoms (see Table 51-2). Myoglobinuria is an important fea-
ture of many other medical conditions: crush injury; extensive infarction of muscle; excessive use or repeated injury of muscles as occurs in status epilepticus, generalized tetanus, malignant neuroleptic syndrome, agitated delirium, prolonged marching, conga drumming, or simply excessive exercise—although the lat-
ter always suggests an underlying metabolic disease of muscle; electrical and lightning injuries; etc. Two noteworthy conditions that are characterized by myonecrosis and myoglobinuria are acute alcoholic intoxication and malignant hyperthermia. The for-
mer is described further on and the latter in Chap. 54, with the membrane channel disorders.

Regardless of the cause of the rhabdomyolysis, the affected muscles become painful and tender within a few hours. Power of contraction is diminished. Sometimes the skin and subcutaneous tissues overlying the affected muscles (nearly always of the limbs and sometimes of the trunk) are swollen and congested. There may be a low-grade fever and leukocytosis. If myoglobinuria is mild, recovery occurs within a few days and there is only a residual albuminuria. When myoglobinuria is severe, renal damage may ensue and lead to anuric renal failure requiring dialysis. The mech-
anism of the renal damage is not entirely clear; probably it is not simply a mechanical obstruction of tubules by precipitated myog-
oblin (although this does occur). It is more likely to result from massive rhabdomyolysis and, correspondingly, there is a very high CK level in the serum.

**Treatment** Alkalization of the urine by ingestion or infusion of sodium bicarbonate is said to protect the kidneys by preventing myoglobin casts, but in severe cases it is of doubtful value, and the sodium may actually be harmful if anuria has already developed. Diuresis induced by mannitol or by loop diuretics such as furosemide and by the administration of intravenous fluids also reduces the chances of anuric renal failure if given in time. Therapy is much the same as for the anuria that follows shock (see Harrison’s Principles of Internal Medicine).

**Statin-Induced Myopathy** With the widespread use of these lipid-lowering medications, myotoxicity has become a well-
described but probably overrated problem. Symptoms range in severity from mild muscular aches with slightly elevated CK con-
centrations in the serum to a rare but potentially fatal rhabdomy-
olitic syndrome. The first generation of these drugs were fungal metabolites (lovastatin, paravastatin, simvastatin) and were infre-
quently implicated in muscle damage, but the new synthetic ones (atorvastatin, fluvastatin, cerivastatin) are more frequently toxic, especially when given with gemfibrizil. (The last of these has re-
portedly led to over 50 deaths from myoglobinuric renal failure and has been removed from the market.) Few cases are this dramatic. This subject has been reviewed by Thompson.

The mechanism of muscle damage is not well understood but it is likely that inherent enzymatic defects are present in a propor-
tion of the severe cases (see the brief review by Farmer). In addi-
tion, the chronic use of statin drugs reduces levels of both ubiqui-
none and small guanosine triphosphate (GTP)-binding proteins, also plausible factors in statin-induced muscle toxicity. As men-
tioned, the combination of one of these medications with gemfi-
brizil is particularly likely to result in muscle damage. Drugs in the statin class with higher lipid solubility appear to have a greater potential for toxicity as a result of their increased muscle penetra-
tion.

A clinical problem arises when the CK level is elevated but the patient taking one of these medications has no muscular symp-
toms. It has been our general practice to continue the medication if the elevation of CK is in the low range and does not rise over time and if the medication is considered necessary. If alternative and safe means of lowering the lipid level are available, then they should be tried in lieu of a statin but each patient’s circumstances differ. In a small series, Phillips and colleagues have called at-
tention to a similarly vexing and not uncommon problem: my-
opathic symptoms such as muscle stiffness, tenderness, and weak-
ness with normal CK concentrations. A trial of discontinuing the medication may be appropriate. Finally, we have encountered a number of patients whose CK levels have remained high for months or longer after the medications have been stopped. In a few of these patients, most otherwise asymptomatic, CK levels have remained high over years but we have had no way to ensure that the test was not abnormal before taking the statin. Noted on page 1134 is a polyneuropathy in which statin drugs have been tentatively implicated.

**Colchicine Myoneuropathy** This condition is included here as much for its clinical interest as for its curious histopathologic fea-
tures. The drug, used widely in the treatment of gout, often gives rise to a mild subacute proximal muscular weakness, but has also produced an acute necrotizing myopathy. Most instances of the latter have occurred in patients with a degree of renal failure, which allows accumulation of the drug (even though the drug is metab-
olized predominantly by the liver). In a few instances it has affected the cranial musculature and the diaphragm. Many cases also show clinical or electrophysiologic evidence of a polyneuropathy as pointed out by Kunc and colleagues, leading to the term colchicine myoneuropathy. The reflexes are diminished and there is mild distal sensory loss. Rare cases of colchicine-induced hypokalemic peri-
odic paralysis and also of myotonia have been reported.

The serum CK concentration may be elevated or normal. The muscle biopsy shows elements of both myopathic and neuropathic disease, with the special feature in muscle of rimmed vacuoles on

SOURCE: Adapted from Sieb by permission (Originally from Victor and Sieb).
Alcoholic Toxic Myopathy  Several forms of muscle weakness have been ascribed to alcoholism. In one type, a painless and predominantly proximal weakness develops over a period of several days or weeks in the course of a prolonged drinking bout and is associated with severe degrees of hypokalemia (serum levels <2 meq/L). The urinary excretion of potassium is not significantly increased; depletion is probably the result of vomiting and diarrhea, which usually precede the onset of muscular weakness. In addition, serum levels of liver and muscle enzymes are markedly elevated. Biopsies from severely weakened muscles show single-fiber necrosis and vacuolation. Treatment consists of the administration of potassium chloride intravenously (about 120 meq daily for several days), after which oral administration suffices. Strength returns gradually in 7 to 14 days, and enzyme levels return to normal concomitantly.

A more dramatic myopathic syndrome, occurring acutely at the height of a prolonged drinking bout, and appropriately termed acute alcoholic myopathy, is manifest by severe pain, tenderness, and edema of the muscles of the limbs and trunk, accompanied in severe cases by renal damage (see Hed et al). Hypokalemia is not implicated. The muscle affection is generalized in some patients and remarkably focal in others. A swollen, painful, tender limb or part of a limb may give the appearance of a deep venous thrombosis or lymphatic obstruction. Myonecrosis is reflected by high serum levels of CK and aldolase and the appearance of myoglobin in the urine, leading in the most severe cases to fatal myoglobinuric renal failure. Indeed, in a general hospital alcoholism is one of the most common causes of rhabdomyolysis and myoglobinuria rivaled only by status epilepticus and trauma. Some patients recover within a few weeks, but others require several months, and relapse during another drinking spree occurs frequently. Restoration of motor power is attendant upon muscle regeneration but may be complicated by polynuropathy and other syndromes of neuromuscular disability associated with alcoholism. Haller and Drachman have produced rhabdomyolysis (with elevated CK and myoglobinuria) in rats by subjecting the animals to a brief fast following a 2- to 4-week exposure to alcohol, suggesting that a similar mechanism may be operative in alcoholic individuals.

Perkoff and his associates described what is presumably a third form of acute muscular disorder in alcoholics, characterized by severe muscular cramps and diffuse weakness, occurring in the course of a sustained drinking bout. They noted a number of biochemical abnormalities in these patients as well as in asymptomatic alcoholics who had been drinking heavily for a sustained period before admission to the hospital—elevated serum levels of CK, myoglobinuria, and a diminished rise in blood lactic acid in response to ischemic exercise, as occurs in McArdle disease. In distinction to the latter, however, myophosphorylase levels were not consistently reduced in the alcoholic patients.

From time to time one observes in alcoholics the subacute or chronic evolution of painless weakness and atrophy of the proximal muscles of the limbs, especially of the legs, with only minimal signs of neuropathy in the distal segments of the legs and feet. Cases such as these have been referred to as chronic alcoholic myopathy, implying a direct toxic effect of alcohol on muscle, but the data are insufficient to warrant such an assumption. Some of these cases have shown necrosis of individual muscle fibers and other signs of polymyositis; most cases seen by the authors have proved to be neuropathic in nature. This has been the experience of others as well (Faris and Reyes; Rossouw et al). Treatment follows along the lines indicated for nutritional-alcoholic neuropathy (page 990), and complete recovery can be expected if the patient abstains from alcohol and maintains adequate nutrition.

VICALE CT: The diagnostic features of a muscular syndrome resulting from hyperparathyroidism, osteomalacia owing to renal tubular acidosis, and perhaps to related disorders of calcium metabolism. *Trans Am Neurol Assoc* 74:143, 1949.

Included under this title are two sizable groups of muscle diseases—one is an assemblage of old congenital deformities that involve muscle, and the other is a unique class of hereditary diseases called congenital myopathies. Insofar as all of the disorders comprising these categories develop in utero, i.e., are congenital, it may be helpful by way of introduction to summarize briefly the main facts about the natural development and aging of muscle. Such diseases are of particular importance in pediatric neurology, for most of them attract notice at an early age.

The Development and Aging of Muscle

The commonly accepted view of the embryogenesis of muscle is that muscle fibers form by fusion of myoblasts soon after the latter differentiate from somatic mesodermal cells. Muscle connective tissue derives from the somatopleural mesoderm. The myoblasts, which are postmitotic, are spindle-shaped mononuclear cells that fuse to form muscle fibers. After fusion, a series of cellular events including the sequential activation of myogenic transcription factors leads to myofibril formation. The newly formed fibers are thin, centrally nucleated tubes (appropriately called myotubes) in which myofilaments begin to be produced from polyribosomes. As myofilaments become organized into myofilbrils, the nuclei of the muscle fiber are displaced peripherally to a subsarcolemmal position. Once the nuclei assume a peripheral position, the myofiber is formed. The detailed mechanisms whereby myoblasts seek one another, the manner in which each of a series of fused nuclei contribute to the myotube, the formation of actin and myosin fibrils, Z-discs, and the differentiation of a small residue of satellite cells on the surface of the fibers are reviewed by Rubenstein and Kelly.

The mechanisms that determine the number and arrangement of fibers in each muscle are not as well understood. Presumably the myoblasts themselves possess the genetic information that controls the program of development, but within any given species there are wide familial and individual variations, which account for obvious differences in the size of muscles and their power of contraction.

The number of fibers assigned to each muscle is probably attained by birth, and growth of muscle thereafter depends mainly on the enlargement of fibers. Although the nervous system and muscleculature develop independently, muscle fibers continue to grow after birth only when they are active and under the influence of nerve. Measurements of muscle fiber diameters from birth to old age show the growth curve ascending rapidly in the early postnatal years and less rapidly in adolescence, reaching a peak during the third decade. After puberty, growth of muscle is less in females than in males, and such differences are greater in the arm, shoulder, and pelvic muscles than in those of the leg; growth in ocular muscles is about equal in the two sexes. At all ages, disuse of muscle decreases fiber size by as much as 30 percent (at the expense of myofibrils), and overuse increases the size by about the same amount (work hypertrophy). Normally, type 1 (oxidative enzyme-rich) fibers are slightly smaller than type 2 (phosphorylative enzyme-rich) fibers; the numerical proportions of the two fiber types vary in different muscles in accordance with their natural functions.

During late adult life, the number of muscle fibers diminishes and variation in fiber size increases. The variations are of two types: group atrophy, in which clusters of 20 to 30 fibers are all reduced in diameter to about the same extent, and random single-fiber atrophy. Also, there is enlargement of other fibers. The exercising of young animal muscle causes a hypertrophy of high-oxidative type 1 fibers and an increase in the proportion of low-oxidative type 2 fibers; aging muscle lacks this capacity—exercise produces only an increase in the proportion of type 2 fibers (Silbermann et al). No such data are available in humans, but clinical observation suggests that with aging, the capacity of muscle to respond to intense, sustained exercise is diminished. Also, muscle cells, like other cells of postmitotic type, are subject to aging changes (lipofuscin accumulation, autophagic vacuolization, enzyme loss) and to death. Group atrophy, present to a slight degree in 90 percent of gastrocnemii in individuals more than 60 years of age, represents denervation effect from an aging-related loss of lumbar motor neurons and peripheral nerve fibers. Further comments regarding muscle and aging can be found in Chap. 29.

Denervation from spinal motor neuron or nerve disease at every age has roughly the same effect—namely, atrophy of muscle fibers (first in random distribution, then in groups) and later, degeneration. Muscle necrosis at all ages excites a regenerative response from sarcolemmal and satellite cells in any intact parts of the fibers. Presumably, if this occurs repeatedly, the regenerative potential wanes, with ultimate death of the fiber—leading to permanent depopulation of fibers with the expected muscle weakness.

CONGENITAL DEFORMITIES INVOLVING MUSCLE

Congenital Fibrous Contractures of Muscle and Joint Deformities

Arthrogryposis (Arthrogryposis Multiplex Congenita) (Table 52-1) Multiple congenital contractures, multiple congenital articular rigidities, and amyoplasia congenita are some of the names that have been applied to congenital deformity and rigidity of many joints. This disorder, now generally referred to as arthrogryposis

| Table 52-1 |
| The main causes of arthrogryposis |
| Werndig-Hoffmann motor neuron disease |
| Myotonic dystrophy |
| Congenital myasthenia gravis (see Chap. 53) |
| Congenital polymyopathy |
| Neonatal neuropathy |
| Prader-Will syndrome |
| Amyoplasia (focal arthrogryposis) |
mental abnormalities of the anterior horn cells (mainly Werdnig-Hoffmann disease, as discussed in Chap. 39) are by far the most common. A failure in development of anterior horn cells results in an uneven smallness and paresis of limb muscles. The unopposed contraction of relatively normally innervated muscles sets the fixed deformities. In a less common group of myopathic causes of arthrogryposis, the nervous system is usually intact and the disease is that of a polymyopathy or congenital muscular dystrophy. It is of interest that in the myopathic variety, the limbs are fixed in a position of flexion at the hips and knees and adduction of the legs, in contrast to the variable postures of the myelopathic (anterior horn cell) form. Also, the latter is more frequently conjoined with multiple anomalies than is the myopathic type. In addition to these two well-recognized types, occasional cases of arthrogryposis are attributable to a neonatal neuropathy, neonatal myasthenia gravis, and the Prader-Willi syndrome (causing intrauterine hypotonia) as noted in Table 52-1.

An infant with arthrogryposis should be evaluated with an electromyogram (EMG) that is interpreted by an experienced electromyographer, and by a biopsy of muscle for the detection of group atrophy and of the congenital polymyopathies described further on in this chapter. Both of these tests are quite difficult to interpret in the premature and term infant with an incompletely formed nervous system. In many circumstances, it is valuable to delay them until several weeks of postterm development. Sometimes the electrophysiologic and biopsy tests may have to be repeated after several weeks or more to give a definitive diagnosis. If the initial evaluations are unrevealing, an imaging study of the brain to detect cerebral malformations and high-resolution banding of chromosome structure (for Prader-Willi syndrome) may prove useful additional tests.

**Congenital Focal Fibrous Contractures** This term refers to a fixation of limb posture due to a developmental lack or destruction of muscles, with shortening and fibrosis of supporting tissue and ligaments. A surprising number of deformities in infants and children are traceable to this type of defect. The most common are congenital clubfoot (talipes), congenital torticollis, congenital elevation of the scapula (Sprengel deformity), and congenital dislocation of the hips. In all these conditions the postural distortion is produced and maintained either by a weakened, fibrotic muscle or by a normal one that is contracted and shortened because of the absence of a countervailing antagonist. Trauma to a muscle during intrauterine life or at birth may lead to fibrosis and to fibrous contracture in some cases.

**Congenital Clubfoot** Here the deformity may be one of plantar flexion of the foot and ankle (talipes equinus), inversion (talipes varus or clubfoot), eversion (talipes valgus or splayfoot), or dorsiflexion of foot and ankle (talipes calcaneus). About 75 percent of all cases are of the equinovarus clubfoot variety (i.e., the foot turns downward and inward). Usually both feet are affected. Multiple incidence in one family may occur. Several explanations of cause and pathogenesis have been offered: fetal malposition, an embryonic abnormality of tarsal and metatarsal bones, a primary defect in nerves or anterior horn cells of the spinal cord, or a congenital dystrophy of muscle. No one theory explains all cases and available pathologic data exclude a single cause and pathogenesis. In some instances clubfoot is the only recognizable congenital abnormality, but more often it occurs as a manifestation of generalized arthrogryposis (see later) and is an indicator of a more widespread involvement of the central nervous system. (See Kakulas and Adams and also Banker for pertinent literature on the subject.)

**Congenital Torticollis (Wryneck)** This disorder begins during the first months of life and, unlike the torticollis of adults discussed in Chap. 6, it is not the result of a dystonia but instead is due to congenital shortening of the sternocleidomastoid muscle, which is firm and taut. The head is inclined to one side and the occiput slightly rotated to the side of the affected muscle. This disorder is nonfamilial and is usually ascribed to injury of the sternocleidomastoid at birth. Whether the injury is a purely mechanical one to the muscle itself or is due to ischemia stemming from arterial or venous occlusion (or an entirely different cause) is not totally clear. It often gives rise to a sternocleidomastoid tumor (actually a pseudotumor) that appears, on exploration, as a pale, spindle-shaped swelling of the muscle belly. The histologic findings are similar to those of Volkman contracture, i.e., replacement of the muscle fibers by relatively acellular connective tissue, suggesting that an ischemic mechanism underlies the defect in some cases.

**Congenital Absence of Muscles (Amyoplasia)**

It is well known that some individuals are born without certain muscles. This pertains not only to certain inconstant and functionally unimportant muscles, such as the palmaris longus, but also to more constant and substantial ones as well. The muscles found to be absent most frequently are the pectoralis, trapezius, serratus anterior, and quadriceps femoris, but many others are missing in isolated cases. Congenital absence of muscle is usually associated with congenital anomalies of neighboring nonmuscular tissues. For example, congenital absence of the pectoral muscle is often accompanied by aplasia or hypoplasia of the mammary or of syndactyly and microactyly. Agenesia of the pectoral muscle may also be associated with scoliosis, webbed fingers, and underdevelopment of the ipsilateral arm and hand (Poland syndrome). Another unusual syndrome consists of congenital absence of portions of the abdominal muscles (“prune belly”), often in association with arthrogryposis and a defect of ureters, bladder, and genital organs. There is also an association in a few cases between a congenital amyoplasia and facioscapulohumeral muscular dystrophy.

**Restricted Nuclear Amyotrophies**

In another group of restricted palsies, the essential abnormality appears to lie in the central nervous system (nuclear amyotrophies). One of the most frequent is congenital ptosis due to an inborn defect of the innervation of the levator palpebrae muscles. Complete paralysis of all muscles supplied by the oculomotor nerve, due apparently to hypoplasia of the third nerve nuclei, may be...
observed in several members of a family and occasionally in only one member. As discussed in Chap. 14, congenital Horner syndrome may be familial; it is associated with depigmentation of the iris (heterochromia iridis). Bilateral abducens palsy is often associated with bifacial palsy in the newborn and is known as the Mobius syndrome; this usually nonfamilial anomaly, the cause of which is thought to be a nuclear hypoplasia or aplasia, is discussed with the developmental disorders (page 873). In these familial nuclear amyotrophies the muscles develop independently of the nervous system but have no prospect of attaining their natural growth and function—and indeed of surviving—because of failure of innervation. It is a kind of congenital denervation hypotrophy. Of course, a primary muscle defect may also give rise to bifacial weakness, as in facioscapulohumeral muscular dystrophy.

**RELATIVELY NONPROGRESSIVE AND SLOWLY PROGRESSIVE CONGENITAL POLYMYOPATHIES**

(See Table 52-2)

Beginning in 1956, with the account by Shy and Magee of a patient whose muscle fibers showed a peculiar central densification of sarcoplasm ("cores"), a new class of hereditary diseases of muscle was delineated. The more common and better-defined members of this group are the central core, nemaline (rod-body), centronuclear myopathies and myofibrillar degeneration, and myopathy with tubular aggregates. As the names imply, in each of these diseases there is no loss of muscle fibers but within each fiber there is a distinctive morphologic abnormality. These illnesses may express themselves early in life by a lack of muscle bulk, hypotonia, weakness of the limbs, and often with additional mild dysmorphic features of other parts of the body. A variety of other morphologic types of congenital myopathy have been described, but they are relatively uncommon and some are of dubious specificity; they are mentioned only briefly.

Further study has revealed that the diseases of this group are not confined to infancy and early childhood and some of them, especially those present at birth, are not as benign as their early descriptions implied. Each of the entities mentioned above has been observed at a later age, even in middle adult life. Indeed, if the disease is mild, there is often no way of deciding whether it had been present since birth.

The characteristic feature of most of these myopathies is lack of progression or extremely slow progression, in contrast to the more rapid pace of many muscular dystrophies, of Werdnig-Hoffmann disease, and of other forms of hereditary motor system disease of childhood and adolescence. Exceptionally, an example of more rapid progression of a congenital myopathy has been reported, and prior to the use of histochemical and electron microscopic techniques, such patients were usually considered to have a "benign muscular dystrophy." Familial occurrence has also been established in some types, so the clinical line of separation between this group of diseases and some of the more slowly progressive muscular dystrophies may in certain cases remain ambiguous. There is no specific treatment for any of the congenital myopathies.

As mentioned earlier, the characteristic lesions in the congenital myopathies are revealed most clearly by the systematic application of histochemical stains to frozen sections and by phase and electron microscopy. Some of the abnormalities are also disclosed by the conventional stains used in light microscopy, but as a group their identification has been the product of newer histologic techniques.

A word of caution is in order about the specificity of some of the morphologic changes and the classifications of the congenital myopathies based upon these changes. It is inadvisable to assume that a change in a single organelle or a subtle change in the sarcoplasm of a muscle fiber can be relied upon to characterize a pathologic process. Indeed, as more careful studies were made of this class of disease, the specificity of the lesions came to be questioned. For example, central cores are sometimes found in the same

AD, autosomal dominant; AR, autosomal recessive; X-linked, X-linked recessive; CK, creatine kinase.
muscle as nemaline bodies, and so on, and each of the denotive lesions has been reported in association with other conditions. Nevertheless, the prominence of the morphologic change in any individual case, along with certain characteristic clinical features, permits an accurate diagnosis to be made.

The main examples of this category are summarized in Table 52-2.

**Central Core Myopathy**  In the original family described by Shy and Magee, five members (four males) in three successive generations were affected, suggesting an autosomal dominant pattern of inheritance. The youngest was 2 years old; the oldest, 65 years. In each, there was weakness and hypotonia soon after birth (“floppy infant”) and a general delay in motor development, particularly in walking, which was not achieved until the age of 4 to 5 years; always the patient had had difficulty in arising from a chair, climbing stairs, and running. The weakness was greater in proximal than in distal muscles, though the latter did not escape, and shoulder-girdle muscles were affected less than those of the pelvic girdle. Facial, bulbar, and ocular muscles were spared. The tendon reflexes were hypoactive and symmetrical. Muscle atrophy was not a prominent feature, though poor muscular development was present in one patient and has since been reported in others. There were no fasciculations, cramps, or myotonia, but cramps following exercise have been described in other families. The electrocardiograms were normal.

The disease is rare, but as additional cases were discovered, milder forms came to be recognized, and in some of them, the symptoms first appeared in adult life. Originally some of these patients were thought to have limb-girdle dystrophy because of the disproportionate involvement of proximal muscles. In other families, such as the one reported by Patterson and colleagues, the disease was first recognized in middle adult life with the rapid evolution of a proximal myopathy. Dislocation of the hips, pes cavus or pes planus, and kyphoscoliosis have been found in a few children. Arthrogryposis is rare. In the majority of cases the progress of the disease is extremely slow, with slight worsening over many years. These represent the two extremes of the process.

The EMG reveals only brief, small-amplitude motor unit potentials with a normal interference pattern. Serum concentration of CK is normal or only slightly elevated, as it is in all the congenital myopathies.

The disease has another remarkable attribute in that every patient is a potential candidate for the development of malignant hyperthermia and should wear a bracelet or be otherwise identified to indicate vulnerability to this anesthetic-induced complication. The gene for central core disease has been mapped to chromosome 19q13.1, where it is linked to the ryanodine receptor gene—a mutation of which is also implicated in the causation of a small number of cases of malignant hyperthermia (see Chap. 54, page 1272).

**Pathologically**, the majority of the muscle fibers appear normal in size or enlarged, and no focal destruction or loss of fibers can be found. The unique feature of the disease is the presence in the central portion of each muscle fiber of a dense, amorphous condensation of myofilbrils or myofilbrillar material. This altered zone characteristically lacks mitochondria and other organelles and gives a positive periodic acid–Schiff (PAS) reaction and a dark blue coloration with the Gomori trichrome stain, contrasting with the normal blue-green color of the peripheral myofilbrils. Within the core, there is a lack of phosphorylase and oxidative enzymes. Most of the cores are in type 1 fibers, which predominate. These cores run the length of the muscle fiber, thus differing from the multiple cores or minicores that are seen in oculopharyngeal and other forms of muscular dystrophy.

**Nemaline (Rod-Body) Myopathy**  This disorder also expresses itself by hypotonia and impaired motility in infancy and early childhood, but—unlike the case in central core disease—the muscles of the trunk and limbs (proximal greater than distal), as well as the facial, lingual, and pharyngeal muscles, are strikingly thin and hypoplastic. Several forms have been observed. One is congenital, with generalized weakness in the neonatal period, making breathing and feeding difficult. The limbs are flaccid and areflexic (“floppy”). Pneumonia and death occur within weeks to months. In forms that permit longer survival, the weakness is less severe, involving mainly the proximal muscles. Tendon reflexes are diminished or absent. The young child with this disease usually suffers from inanition and frequent respiratory infections, which may shorten life. Strength slowly improves with growth, the latter process evidently counteracting the advance of the disease.

A slender appearance, narrow face, open mouth, narrow, arched palate, and kyphoscoliosis are regular but not invariable accompaniments of nemaline myopathy. These dysmorphic features are not typical of the other congenital polymyopathies. Pes cavus or clubfoot may be added. Some of the milder cases reach adulthood, at which time a cardiomyopathy may threaten life. A. G. Engel as well as W. K. Engel and Reznick have observed in individuals who first showed signs of the disease in middle age; the weakness was mainly in proximal muscles and the dysmorphic and skeletal abnormalities of the childhood form were lacking. The EMG is “myopathic,” and serum enzymes are normal or only slightly elevated.

Cases of nemaline myopathy have come to attention during adulthood in which there is disproportionate involvement of the respiratory muscles (a feature shared with the adult appearance of acid maltase deficiency). Usually, there had been a history of poor physical performance through earlier life.

Nemaline myopathy appears to be genetically heterogeneous. The pattern of inheritance is most often autosomal dominant, with variable penetrance. In some families there has been an autosomal recessive or an X-linked pattern of inheritance. Studies of the various gene defects have begun to clarify the uncertainties about inheritance and explain the relationships between the different forms of the disease. The genes implicated in nemaline myopathy include alpha-tropomyosin, beta-tropomyosin, alpha-actin, nebulin, tropinin, and the ryanodine receptor (the last of these is more commonly implicated in central core disease, as mentioned earlier; see Table 52-1).

The disease is so named for the rods or coils of thread-like structures in pathology material. Frozen muscle tissue stained with Gomori trichrome discloses the characteristic lesion, which can be seen under the light microscope. Myriads of bacillus-like rods, singly and in small packets, are seen beneath the plasma membrane of the muscle fiber. They are composed of material that resembles that of Z bands under the electron microscope, and often actin filaments are attached, just as they are to Z bands. The type 1 fibers, which usually predominate, are smaller than normal, as in central core disease. The size of the motor neurons has been reported to be reduced. The weakness is probably related to a smallness and reduction in the number of muscle fibers and possibly to focal interruption of their cross- striations, particularly the Z bands.
Centronuclear or Myotubular Myopathy  In this familial disease, hypotonia and weakness become manifest soon after birth or in infancy or early childhood. Rarely, in the mildest form, the diagnosis does not become evident until adult years. All the striated skeletal muscles are involved to some degree, but distinctive features are ptosis and ocular palsies combined with weakness of facial, masticatory, lingual, pharyngeal, laryngeal, and cervical muscles in most of the infants with this disease, but not in adults. In the limbs, distal weakness keeps pace with proximal weakness. The limbs remain thin and areflexic throughout life. Motor development is necessarily retarded, though some improvement with maturation can occur; later, however, motor functions that had been acquired may be lost as the disease slowly advances. Several patients have shown signs of cerebral abnormality, with seizures and an abnormal electroencephalogram (EEG), but this may not be part of the disease. Needle EMG examination shows the usual myopathic pattern, as well as positive sharp waves and fibrillation potentials in some cases. Abundant spontaneous activity should suggest the diagnosis of centronuclear myopathy (Griggs et al).

Heckmatt and colleagues have classified this disorder into three types, based on severity, mode of presentation, and genetic pattern: (1) a severe neonatal X-linked recessive type; (2) a less severe early-infantile, late-infantile, or childhood autosomal recessive type; and (3) a still milder late childhood—adult autosomal dominant type. The primary defect in the X-linked form is a mutation in the gene that encodes a protein designated myotubularin; presumably this plays a role in myotube maturation. At least one autosomal dominant form has been ascribed to mutations in the protein MYF6, a helix-loop-helix protein that appears to function as a myogenic transcription factor.

The outstanding pathologic features of the disease are the smallness of muscles and their constituent fibers and central nucleation. In one group of centronuclear myopathies, there is hypotrophy of type 1 fibers (Bethlem et al, Karpati et al). Surrounding most of the centrally placed nuclei is a clear zone, in which there is a lack of organization of contractile elements. Because of central nucleation, the disease has incorrectly been referred to as myotubular myopathy, implying an arrest in development of muscle at the myotubular stage. Actually, the nature of the pathologic process is obscure. The small, centrally nucleated fibers do not really resemble typical myotubes. Also, there is evidence from electron microscopic studies of changes in the central parts of the fibers (lack of enzymatic activity in the clear zones surrounding the nuclei), leading in all probability to fiber loss. Such changes argue against a purely developmental abnormality.

Myopathy with Tubular Aggregates  The accumulation of tubular aggregates in the subsarcolemmal or more interior regions of muscle fibers was first observed in patients with hypokalemic periodic paralysis and myotonia congenita and later with a number of diverse conditions, such as chronic drug intoxication, hypoxia, and congenital myasthenic syndromes. However, tubular aggregates are also the defining feature of several purely myopathic syndromes: (1) A slowly progressive muscular weakness, in a limb-girdle distribution, with onset in childhood or early adult life; inheritance is either autosomal dominant or recessive in type. (2) A childhood onset of proximal weakness, easy fatigability, and myasthenic features; heredity is autosomal recessive. This syndrome may respond to pyridostigmine. (3) Muscle pain, cramps, and stiffness induced by exercise; the cases to date have been sporadic.

The histologic changes are readily overlooked in paraffin sections. Cryostat sections show masses of material that is basophilic with hematoxylin and eosin and bright red with Gomori trichrome and shows an intense reaction with NADH dehydrogenase. By electron microscopy, the bundles of tubular aggregates are sharply demarcated from myofibrils.

Other Congenital Myopathies  The foregoing congenital myopathies—central core, nemaline, centronuclear, and tubular aggregate types—are well-defined clinicopathologic entities. In addition, other far less common types have been described, each named according to a distinctive dysmorphic alteration of organelles in muscle fibers in histochemical and electron microscopic preparations. In none of these additional types has the pattern of inheritance or the gene locus been identified. Some of these myopathies—multicore (minicore), fingerprint body, sarcotubular—have been reported in only a few cases, quite insufficient to allow their categorization as disease entities. Two other types—congenital fiber type disproportion and congenital fiber type predominance—originally designated as congenital myopathies, have proved to be nonspecific histochemical alterations observed in many infants and children with congenital developmental abnormalities, delays in motor development, and other conditions. Other putative congenital myopathies include so-called reducing body, trilaminar, and cap disease; zebra body; and familial myopathy with lysis in type 1 fibers, among others. They most likely represent nonspecific reactions in muscle or fixation artifacts; as yet there is no evidence that any one of them represents a clinicopathologic entity.

Myofibrillar Myopathy  Beyond the uncertain entities noted earlier, the field of chronic myopathies has been muddied by a plethora of reports describing a variety of curious inclusions in muscle fibers, under a bewildering array of terms: myopathy with inclusion bodies, atypical myopathy with myofibrillar aggregates; autosomal dominant myopathy with myofibrillar inclusions; cardiokaleidoscopic myopathy with intrasarcoplasmic dense granuloflamentous material; cytoplasmic body myopathy; spheroid body myopathy; myopathy with characteristic sarcoplasmic bodies and skeleton (desmin) filaments; myopathy with Mallory-body-like inclusions; and familial cardiomyopathy with subsarcolemmal vermiform deposits. Implicated by these reports was the notion that each of these structural abnormalities represented a new and distinctive myopathy.

More recently, in a careful light microscopic evaluation of both published reports and their own cases, Nakano and Engel and their colleagues have convincingly demonstrated that the many reported structural changes were the consequence of a single pathologic process—a focal dissolution of myofibrils, followed by an accumulation of the products of the degradative process. These authors proposed the term myofibrillar myopathy to encompass the entire spectrum of these pathologic changes. Mutations of one of the various proteins that relate to the Z-disc (the connection between adjacent sarcomeres, which are the structural units of the myofibril) of muscle seem to be the unifying feature. Many of these abnormalities can be traced to a dominant mutation in the genes coding for the filament proteins myotilin and desmin and in the chaperone protein \( \alpha \beta \)-crystallin, as described in the review by Selen and colleagues cited later. Presumably, mutations in either gene predispose to protein aggregation, the former by destabilizing desmin and the latter by altering the capacity of the \( \alpha \beta \)-crystallin to facilitate normal desmin folding.
The diagnosis of myofibrillar myopathy (by biopsy) is usually made in adult life. Men and women are equally affected. Slowly progressive weakness of the muscles of limbs and trunk is the main clinical feature. Both proximal and distal muscles are affected, more in the legs than in the arms. Hyporeflexia is usual. Cardiac involvement, usually abnormalities of conduction, is present in about one quarter of the patients. The pattern of inheritance is most often autosomal dominant, but autosomal recessive and X-linked patterns also have been described. An astonishing 63 patients have been studied by Selcen and associates; their article can be consulted for further details.

Genetically there is considerable heterogeneity. At the time of writing, no fewer than five chromosomal loci for myofibrillar myopathy have been documented, and more are likely to exist (Engel). Predictably, therefore, a more sharply defined disease or diseases will emerge with further study of the category of myofibrillar myopathy.

As stated in the introductory section, there is currently no treatment for any of the congenital polymyopathies.

REFERENCES

THE SPINAL MUSCULAR ATROPHIES OF INFANCY AND CHILDHOOD

Obviously this important group of diseases, appearing as they do in the same periods of life as the congenital polymyopathies and of certain of the congenital muscular dystrophies, must figure in the differential diagnosis of early-onset muscle weakness, hypotonia, and of arthrogryposis. Indeed, they represent the main problems faced by the clinical myologist studying diseases of the infant and child. Their hereditary nature, their progression to fatal outcome or delayed motor attainments, and their tendency in certain instances to produce disabling contractures are shared with the primary muscle diseases. Fortunately the proper application of current laboratory techniques sets them apart in most instances. In deference to their neuronal origin, the authors have decided to place them with the other degenerative diseases (see pages 945 to 947).
CHAPTER 53

MYASTHENIA GRAVIS AND RELATED DISORDERS OF THE NEUROMUSCULAR JUNCTION

Included under this title is a group of diseases affecting the neuromuscular junction, the most important of which is myasthenia gravis. As a group, these disorders exhibit several characteristic and striking features, the essential one being a fluctuating weakness and fatigability of muscle. Some degree of weakness is usually present at all times, but it is made worse by activity. The weakness and fatigability reflect physiologic abnormalities of the neuromuscular junction that are demonstrated by clinical signs and by special electrophysiologic testing. As an aid to understanding the diseases discussed in this chapter, the reader should consult the discussion of the structure and function of the neuromuscular synapse given in Chap. 48.

MYASTHENIA GRAVIS

The main feature of myasthenia gravis, referred to simply as myasthenia, is a fluctuating weakness of certain voluntary muscles, particularly those innervated by motor nuclei of the brainstem, i.e., ocular, masticatory, facial, deglutitional, and lingual. Manifest weakening during continued activity, quick restoration of power with rest, and dramatic improvement in strength following the administration of anticholinesterase drugs such as neostigmine are the other notable characteristics of the weakness.

Historical Note Several students of medical history affirm that Willis, in 1672, gave an account of a disease that could be none other than myasthenia gravis. Others give credit to Wilks (1877) for the first description and for having noted that the medulla was free of disease, in distinction to other types of bulbar paralysis. The first reasonably complete accounts were those of Erb (1878), who characterized the disease as a bulbar palsy without an anatomic lesion, and of Goldflam (1893); for many years thereafter, the disorder was referred to as the Erb-Goldflam syndrome. Jolly (1895) was the first to use the name myasthenia gravis, to which he added the term pseudoparalytica to indicate the lack of structural changes at autopsy. Also it was Jolly who demonstrated that myasthenic weakness could be reproduced in affected patients by repeated faradic stimulation of the relevant motor nerve and that the “fatigued” muscle would still respond to direct galvanic stimulation of its membrane. Interestingly, he suggested the use of physostigmine as a form of treatment, but there the matter rested until Reman, in 1932, and Walker, in 1934, demonstrated the therapeutic value of the drug. Campbell and Bramwell (1900) and Oppenheim (1901) each analyzed over 60 cases and crystallized the clinical concept of the disease. The relationship between myasthenia gravis and tumors of the thymus gland was first noted by Laquer and Weigert in 1901, and in 1949 Castleman and Norris gave the first detailed account of the pathologic changes in the gland.

In 1905 Buzzard published a careful clinicopathologic analysis of the disease, commenting on both the thymic abnormalities and the infiltrations of lymphocytes (called lymphorrhages) in muscle. He postulated that an "autotoxic agent" caused the muscle weakness, the lymphorrhages, and the thymic lesions. He also commented on the close relation of myasthenia gravis to Graves disease and Addison disease, which are all now considered to have an autoimmune basis. In 1960, Simpson and, independently, Nastuk and coworkers theorized that an autoimmune mechanism must be operative in myasthenia gravis. Finally, in 1973 and subsequently, the autoimmune nature of myasthenia gravis was established through a series of investigations by Patrick and Lindstrom, Fambrough, Lennon, and A. G. Engel and their colleagues (see further on, under "Etiology and Pathogenesis").

These and other references to the early historical features of the disease are to be found in the reviews by Viets and by Kakulas and Adams; A. G. Engel's monograph (1999) is an excellent modern reference.

Clinical Manifestations

Myasthenia gravis, as the name implies, is a muscular weakness formerly with a grave prognosis. Repeated or persistent activity of a muscle group exhausts its contractile power, leading to a progressive paresis, and rest restores strength, at least partially. These are the identifying attributes of the disease; their demonstration, assuming that the patient cooperates fully, is sometimes enough to establish the diagnosis.

The special vulnerability of certain muscles gives myasthenia a characteristic stamp. Usually the eyelids and the muscles of the eyes—and somewhat less often of the face, jaws, throat, and neck—are the first to be affected. Infrequently the initial complaint is referable to the limbs. More specifically, the weakness of the levator palpebrae or extraocular muscles is the initial manifestation of the disease in about half the cases, and these muscles are involved eventually in more than 90 percent. Ocular palsies and ptosis (weakness of eyelid opening) are usually accompanied by weakness of eye closure, a combination that is virtually always myopathic and not neuropathic in origin, e.g., observed in myasthenia and muscular dystrophy. Diplopia in myasthenia does not correspond to the innervatory pattern of a nerve but is the result instead of asymmetric weakness of several muscles in both eyes. As the disease advances, it often spreads from the cranial to the limb and axial muscles. The onset of weakness is usually insidious, but there are instances of fairly rapid development, sometimes apparently initiated by an emotional upset or infection (usually respiratory). In most patients, however, a precipitating event cannot be identified. Symptoms may first appear during pregnancy or, more commonly, in the puerperium or in response to drugs used during anesthesia. Thymic abnormalities of several types are closely connected with the disease, as elaborated further on, and weakness may begin months or years after removal of a thymoma.

Certain ocular signs are highly characteristic of myasthenia. Sustained upgaze for 30 or more seconds will usually induce or exaggerate ptosis and may uncover a myasthenic ocular motor
weakness. Cogan described a twitching of the upper eyelid that appears a moment after the patient moves the eyes from a downward to the primary position (“lid-twitch” sign). Or, after sustained upward gaze, one or more twitches may be observed with closure of the eyelids or during horizontal movements of the eyes. Repeated ocular versions induced by tracking a target or by an optokinetic stimulus may disclose progressive paresis of the muscles that carry out these movements. Unilateral painless ptosis without ophthalmoplegia or pupillary abnormality in an adult will most often prove to be due to myasthenia. Usually there is subtle ptosis of the other eye that can be revealed by manually elevating the more affected eyelid. Attempts by the patient to overcome the ptosis may impart a staring expression of the opposite eye. Bright sunlight is said to aggravate the ocular signs and cold, to improve them. The application of an ice pack over the eye often relieves the ptosis for a brief period.

Muscles of facial expression, mastication, swallowing, and speech are affected in 80 percent of patients at some time in the illness, and in 5 to 10 percent these are the first or only muscles to be involved. Less frequent is an initial or early involvement of the flexors and extensors of the neck, muscles of the shoulder girdle, and flexors of the hips. (This pattern may be associated with a special autoantibody as discussed later.) Of the trunk muscles, the erector spinae are the most frequently affected. In the most advanced cases, all muscles are weakened, including the diaphragmatic, abdominal, and intercostal muscles and even the external sphincters of the bladder and bowel. The involvement of any group of muscles closely parallels their degree of weakness early in the disease. The clinical rule holds that the proximal muscles are far more vulnerable than distal ones, as they are in almost all other forms of myopathy.

The other characteristic feature of myasthenic weakness is its tendency to increase as the day wears on or with repeated use of an affected muscle group, but patients seldom volunteer this information. A few patients report being paradoxically worse on awakening, especially if they have not received medication during the night. In broad terms, therefore, myasthenia gravis may be conceived as a fluctuating and fatigable oculofaciobulbar palsy.

To reiterate the topographic attributes of the illness, combined weakness of the extraocular muscles, levators, and orbicularis oculi combined with normal pupillary responses to light and accommodation is virtually diagnostic of myasthenia, especially if the function of these muscles is restored after a period of rest. Facial mobility and expression are altered: the natural smile becomes transformed into a snarl; the jaw may sag, so that it must be propped up by the patient’s hand; chewing tough food may be difficult, and the patient may have to terminate a meal because of inability to masticate and swallow. It may be more difficult to eat after talking, and the voice fades and becomes nasal after sustained conversation. Women may complain of inability to fix their hair or makeup because of fatigue of the shoulders, or of difficulty in applying lipstick because they are unable to purse and roll their lips. Weakness of the neck muscles causes fatigue in holding up the head. In cases with generalized weakness, there may be difficulty in retaining posture because of weakness of the external sphincter.

A temporary increase in weakness may follow vaccination, menstruation, and exposure to extremes of temperature. A peculiarity of myasthenic muscle contraction that may be observed occasionally is a sudden lapse of sustained posture or interruption of movement resulting in a kind of irregular tremor, similar to that of normal muscle nearing the point of exhaustion. A dynamometer demonstrates the rapidly waning power of contraction of a series of hand grips, and repetitive stimulation of a motor nerve at slow rates while recording muscle action potentials the same decremental strength in a more quantitative fashion (see Fig. 45-5A and further on).

Weakened muscles in myasthenia gravis undergo atrophy to only a minimal degree or not at all. Tendon reflexes are seldom altered. Even repeated tapping of a tendon does not usually tax muscles to the point where contraction fails. Smooth and cardiac muscles are not involved and other neural functions are preserved. The tendon reflexes are unaffected. Weakened muscles, especially those of the eyes and back of the neck, may ache, but pain is seldom an important complaint. Paresthesias of the face, hands, and thighs are reported infrequently but are not accompanied by demonstrable sensory loss. Anosmia and ageusia have been mentioned as rare findings, but they may be coincidental. The tongue may display one central and two lateral longitudinal furrows (trident tongue), as pointed out originally by Buzzard.

Certain epidemiologic features of the disease are of clinical interest. Its prevalence is variously estimated to be from 43 to 84 per million of the population and the annual incidence rate, approximately 1 per 300,000. The disease may begin at any age, but onset in the first decade is relatively rare (only 10 percent of cases occur under the age of 10 years). The peak age of onset is between 20 and 30 years in women and between 50 and 60 years in men. Under the age of 40, females are affected two to three times as often as males, whereas in later life, the incidence in males is higher (3:2). Of patients with thymomas, the majority are older (50 to 60 years), and males predominate.

To facilitate clinical staging of therapy and prognosis, the following classification, introduced by Osserman, remains useful (the relative incidence of each type is indicated and “drug response” refers to treatment with an anticholinesterase):

I. Ocular myasthenia (15 to 20 percent)

II. A. Mild generalized myasthenia with slow progression; no crises; drug-responsive (30 percent)

B. Moderately severe generalized myasthenia; severe skeletal and bulbar involvement but no crises; drug response less than satisfactory (25 percent)

III. Acute fulminant myasthenia; rapid progression of severe symptoms with respiratory crises and poor drug response; high incidence of thymoma; high mortality (15 percent)

IV. Late severe myasthenia; symptoms same as III, but resulting from steady progression over 2 years from class I to class II (10 percent)

Others, for example Compston and colleagues have proposed a classification based on a constellation of the age of onset, presence or absence of thymoma, antibody level against acetylcholine receptors (AChR), and association with HLA haplotypes: (1) myasthenia gravis with thymoma—no sex or HLA association, high AChR antibody titer; (2) onset before age 40, no thymoma—female preponderance and an increased association with HLA A1, B8, and DRW3 antigens; (3) onset after age 40, no thymoma—male preponderance, increased association with HLA A3, B7, and DRW2 antigens, low AChR antibody titer. The last group includes a proportion of older men with purely ocular symptoms (Osserman type I). Classifications such as these are meant to capture certain types or contexts of myasthenia more than to convey the severity of illness.
The course of the illness is extremely variable. Rapid spread from one muscle group to another occurs in some, but in others, the disease remains unchanged for months before progressing. Remissions may take place without explanation, usually in the first years of illness, but these happen in less than half the cases and seldom last longer than a month or two. If the disease remits for a year or longer and then recurs, it then tends to be progressive. Relapse may be occasioned by the same events that preceded the onset of the illness, especially infections. In Simpson’s opinion, and this coincides with our observations, the danger of death from generalized myasthenia gravis is greatest in the first year after onset of the disease. A second period of danger in progressive cases is from 4 to 7 years after onset. After this time the disease tends to stabilize and the risk of severe relapse diminishes. Fatalities relate mainly to the respiratory complications of pneumonia and aspiration. The mortality rate in the first years of illness, formerly in excess of 30 percent, is now less than 5 percent, and with appropriate therapy, most patients are able to lead productive lives. The course is altered by thymectomy (as discussed further on).

One aspect of interest is the timing and frequency of conversion from ocular and restricted oropharyngeal patterns of weakness to more widespread involvement including the diaphragm. Bever and coworkers have confirmed the general impression that an increasing duration of purely ocular myasthenia is associated with a decreasing risk of late generalization of weakness. These authors found in a retrospective study of 108 patients that only 15 percent of the observed instances of generalization occurred after 2 years of isolated ocular manifestations. A later age at onset was also associated with a higher incidence of fatal respiratory crises. In general, patients whose disease begins at a younger age run a more benign course. Grob and colleagues, who recorded the course of an astonishing 1036 patients for a mean duration of 12 years, found that the clinical manifestations remained confined to the extraocular muscles and orbiculares oculi in 16 percent. Their data further indicated that if localized ocular myasthenia had been present for only a month, there was a 60 percent likelihood that the disease would become generalized, but in those cases that remained restricted for more than a year, only 16 percent became generalized. In contrast, of 37 consecutive cases carefully studied by Weinberg and colleagues in our clinic with only ocular signs, 17 became generalized within a period of 6 years. Also informative in Grob’s series was that in two-thirds of 750 patients with generalized weakness, the disease attained its maximum severity within a year of onset, and in 83 percent, within 3 years. It has been stated that the progression of symptoms is more rapid in male than in female patients.

With regard to prognosis, it is not widely recognized that isolated muscle groups may occasionally remain permanently weak even when the ocular and generalized weakness has resolved. The muscles most often affected in this way are the anterior tibialis, triceps, and portions of the face.

The long-term outlook for children with myasthenia is better than it is for adults, and their life expectancy is only slightly reduced. Rodriguez and colleagues followed a group of 149 children for an average of 17 years; 85 of them had thymectomies, one of the main treatments for myasthenia as discussed further on. Approximately 30 percent of the nonthymectomized and 40 percent of the thymectomized patients underwent remission and were free of symptoms, usually in the first 3 years of illness. Those children with bulbar symptoms and no ocular or generalized weakness had the most favorable outcome.

The special and relatively common problem of myasthenic crisis is discussed in a later section.

Thymic and Other Disorders Associated with Myasthenia Thyinic tumors occur in 10 to 15 percent of patients with myasthenia gravis, and a nonneoplastic lymphofollicular hyperplasia of the thymic medulla occurs in 65 percent or more. Thymomas with malignant characteristics may spread locally in the mediastinum and to regional lymph nodes, but they rarely metastasize beyond these structures; when they do spread, the lungs and liver are usually affected. It should be emphasized that thymic tumors may be missed in plain films of the chest and should be sought by CT scanning. The significance of thymic disorders is discussed further on.

Although not directly relevant to myasthenia, it is of interest to neurologists that a number of other curious neurologic disorders occur in association with thymoma. Among our own cases over the years were two instances of a “limbic encephalitis” with memory loss and confusion that could not be differentiated from the better-described paraneoplastic variety of encephalitis (page 585), one case of midbrain encephalitis, one of Morvan’s fibrillary chorea (discussed in the following chapters), and one of aplastic anemia. Such cases appear in the literature from time to time and all are thought to have a humoral immune basis.

Of biologic importance is the coexistence of myasthenia gravis and other autoimmune diseases. Thyrotoxicosis (5 percent of myasthenic patients—page 1236), lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, mixed connective tissue disease, anticardiolipin antibody, and (curiously) polymyositis have all been associated with myasthenia more often than can be explained by chance. A large proportion of young women with myasthenia have moderately elevated titers of antinuclear antibody without the clinical manifestations of systemic lupus.

Familial occurrence of myasthenia is known, but it is rare. Many such cases prove to have one of the rare genetically determined myasthenic syndromes and not the acquired autoimmune form of disease (see further on). More common is a family history of one of the other autoimmune diseases enumerated earlier. For example, in the series reported by Kerzin-Storrar and associates, 30 percent had a maternal relative with one of these disorders of clearly established autoimmune nature, suggesting that myasthenia gravis patients inherit a susceptibility to autoimmune disease. There have also been numerous case reports of the concurrence of myasthenia and multiple sclerosis, again suggesting a common autoimmune basis, but the statistical association here is less certain.

Pathologic Features of the Thymus and of Muscle Reference has already been made to the prominent involvement of the thymus gland in myasthenia gravis. As mentioned, true neoplasms of the gland are found in about 10 to 15 percent of patients, but of greater import is that fully 65 percent of the remaining patients show a striking degree of hyperplasia of the medulla of the thymus characteristic by lymphoid follicles with active germinal centers. Hyperplasia is even more frequent in younger patients in the third and fourth decades. The cells in the centers of the follicles are histocytes; they are surrounded by helper T lymphocytes, B lymphocytes, and plasma cells; and immunoglobulin G (IgG) is elaborated in the germinal follicles. These resemble the cellular reaction that is observed in the thyroid of Hashimoto thyroiditis. Since the latter disease has been reproduced in animals by injecting extracts of thyroid with Freund adjuvants, it has been suggested that the so-
called thymitis of myasthenia gravis is the result of a similar autoimmune sensitization but the inciting events for this process are entirely unknown. Immunosuppression with steroids causes involution of the thymus.

With regard to thymic tumors, two forms have been described: one composed of histiocytic cells like the reticulum cells in the center of the follicles, and the other predominantly lymphocytic and considered to be lymphosarcomatous. Some of the tumors have a high proportion of spindle-shaped cells. Overlapping types have been common in our material. Thymic tumors may be unattended by myasthenia, though myasthenia has eventually developed in all of our cases, sometimes 15 to 20 years after the tumor was first recognized and removed surgically. According to Brill et al, the severity of myasthenic symptoms is no different in patients with thymoma than it is from that in patients without a tumor, but our impression has been that patients with tumors, particularly children, sometimes have a peculiar clinical course; we have observed with some frequency unexpected sudden remissions and severe relapses, as well as resistance to medications.

Many contemporary studies, including over 40 autopsies at our hospitals, have confirmed Erb’s original contention that myasthenia gravis is a disease without a central nervous system lesion. The brain and spinal cord are normal unless damaged by hypoxia and hypotension from cardiorespiratory failure. Furthermore, the muscle fibers are generally intact, although in fatal cases with extensive paralysis, isolated fibers of esophageal, diaphragmatic, and eye muscles may undergo segmental necrosis with variable regeneration (Russell). Scattered aggregates of lymphocytes (lymphorrhages) are also observed, as originally noted by Buzzard, but none of these changes in muscle explain the widespread and severe weakness. The lymphorrhages, which are found more frequently in the tumor cases, are not confined to the vicinity of the motor end plates.

The main ultrastructural alterations occur in the motor end plate. These changes, elegantly demonstrated by A. G. Engel and associates, consist of a reduction in the area of the nerve terminal, a simplification of the postsynaptic region (sparse, shallow, abnormally wide or absent secondary synaptic clefts) and a widening of the primary synaptic cleft (Fig. 53-1). However, the number and size of the presynaptic vesicles and their quanta of ACh are within the normal range. The observation of regenerating axons near the junction, the many simplified junctions, and the absence of nerve terminals supplying some postsynaptic regions suggested to Engel and coworkers that there was an active process of degeneration and repair of the neuromuscular junction, particularly of the postsynaptic side.

**Etiology and Pathogenesis** The clear demonstration of an immunologic mechanism operative at the neuromuscular junction has been the most significant development in our understanding of myasthenia gravis. Patrick and Lindstrom discovered that repeated immunization of rabbits with AChR protein obtained from the electric eel caused a muscular weakness (contrary to what is stated in some books, their discovery was not accidental). Lennon and colleagues recognized this model as being similar to that of myasthenia gravis. Soon thereafter Fambrough and coworkers demonstrated that the basic defect in myasthenia gravis was a marked reduction in the number of AChR on the postsynaptic membrane of the neuromuscular junction. These observations were followed...
by the creation of an experimental model of the disease and the
demonstration that experimentally induced myasthenia had clinical,
pharmacologic, and electrophysiologic properties identical with those of human myasthenia gravis—i.e., decreased miniature
end-plate potentials (MEPPs), decremental response on neuromus-
cular stimulation at 3 Hz, and correlation of weakness with the
number of labeled antibodies attached to the receptor sites (Engel
et al). It was also shown that humoral antibodies directed against
protein components of AChR could transfer the myasthenic weak-
ness to normal animals and that the weakness as well as the phys-
iologic abnormalities could be reversed by the administration of
anticholinesterase drugs. Thus, the accumulated evidence satisfied
the criteria for the diagnosis of an autoantibody-mediated disorder
(Drachman).

The present view is that myasthenic weakness and fatigue are
due to the failure of effective neuromuscular transmission on the
postsynaptic side. The greatly reduced number of receptors and the
competitive activity of anti-AChR antibodies (see later) produce
end-plate potentials of insufficient amplitude to generate action po-
tentials in some nerve fibers. By the cumulation of blocked trans-
mission at many end plates, there results a reduction in the con-
trollable power of the muscle. This deficiency is reflected first in the
ocular and cranial muscles, the ones that are both the most continu-
ously active muscles and have the fewest AChR per motor unit.
Fatigue is understandable as the result of the normal decline in the
amount of ACh released with each successive impulse.

Antibodies to AChR protein are present in over 85 percent of
patients with generalized myasthenia and in 60 percent of those
with ocular myasthenia (Newsom-Davis). Antibodies are also
present in infants with neonatal myasthenia gravis and in animal
species known to have a naturally occurring myasthenia. The pres-
ence of receptor antibodies has proved to be a reasonably sensitive
and reliable test of the disease, as discussed later under “Measure-
ment of Receptor Antibodies in Blood.” The manner in which an-
tibodies that are situated in the intracellular compartment (such as
MusK discussed below) cause weakness is not known.

How the antibodies act at the receptor surface of the end plate
has also been investigated, but the matter is complex. Neuromus-
cular transmission is probably impaired in several ways: (1) The
antibodies may block the binding of ACh to the AChR. (2) Serum
IgG from myasthenic patients has been shown to induce a two-
to threefold increase in the degradation rate of AChR. This may be
the result of the capacity of antibodies to cross-link the receptors,
which are gathered into clusters in the muscle membrane and then
internalized by a process of endocytosis and degraded. (3) Anti-
bodies may cause a complement-mediated destruction of the post-
synaptic folds (Engel and Arahata). The latter two mechanisms
would be expected to reduce the number of AChR at the synapse.

Although the evidence that an autoimmune mechanism is re-
sponsible for the functional disorder of muscle in myasthenia gravis
is incontrovertible, the source of the autoimmune response has not
been established. Because most patients with myasthenia have thym-
ic abnormalities and a salutary response to thymectomy, it is
logical to implicate the lymphoid reaction in this gland in the patho-
genesis of the disease. Both T and B cells from the myasthenic
thymus are particularly responsive to the AChR, more so than anal-
ogous cells from peripheral blood. Moreover, the thymus contains
“myoid” cells (resembling striated muscle) that bear surface AChR.
However, it is not known with certainty that thymic myoid cells
are the foci of immunologic stimulation in myasthenia gravis. The
most obvious objection is that such cells are even more abundant
in the normal than in the myasthenic thymus (according to Schluep
et al). Another suggested pathogenesis, yet unconfirmed, is that a
virus with a tropism for thymic cells might injure such cells and
induce antibody formation. A viral infection might at the same time
have a potential for oncogenesis, accounting for thymic tumors, but
this is all speculative. Scadding and associates have suggested a
somewhat different mode of thymic involvement; they have shown that
thymic lymphocytes from patients with myasthenia gravis can
synthesize anti-AChR antibody, both in culture and spontaneously.

Diagnosis In patients who present with a changeable diplopia and
the typical myasthenic facies—unequally drooping eyelids, rela-
tively immobile mouth turned down at the corners, a smile that
looks more like a snarl, a hanging jaw supported by the hand—
the diagnosis can hardly be overlooked. However, only a minority
of patients present in this stage of the disease, and infrequently is
there a clear recognition, even by the patient, that the muscles tire
during activity and as the day progresses. Ptosis, diplopia, difficulty
in speaking or swallowing, or weakness of the limbs are at first
mild and inconstant and may be mistaken for a cerebrovascular
disease. However, the finding that sustained activity of small cran-
ial muscles results in weakness (e.g., increasing droop of eyelids
while looking at the ceiling or diplopia when fixating in lateral or
vertical gaze or reading for 2 to 3 min) and that contraction im-
proves after a brief rest is virtually diagnostic, even in the early
stages of the disease. Any other affected group of muscles may be
critically tested in similar fashion. The characteristic ocular signs
have already been described. For confirmation, or if the diagnosis
remains in doubt, the measurement of specific antibody (anti-
AChR), electromyography, and certain pharmacologic tests de-
dscribed below are necessary. Several special diagnostic problems
are summarized further on.

Electrophysiologic Testing Characteristic of myasthenia is a
rapid reduction in the amplitude of compound muscle action poten-
tials evoked during a series of repetitive stimulations of a pe-
ipheral nerve at a rate of 3 per second (decrementing response as
shown in Fig. 45-5A). Reversal of this response by neostigmine or
erdoprophonium has been a reliable confirmatory finding in most
cases. A decremental response to stimulation can usually be ob-
tained from the facial, hand, or proximal limb muscles, which may
or may not be clinically weak. During a progressive phase of the
disease or during steroid therapy, a slight initial incrementing re-
sponse may be obtained, not to be confused with the marked in-
crementing response after voluntary contraction that characterizes
the Lambert-Eaton syndrome (see further on).

Single-fiber electromyography (EMG) represents an even
more sensitive method of detecting the defect in neuromuscular
transmission. This technique demonstrates an inconstancy of the
normally invariant interval between the firing of fibers connected
to the same motor unit (“jitter”—see page 1106) or a blocking of
successive discharges from single muscle fibers belonging to the
same motor unit. The test requires a great deal of cooperation from
the patient; it requires that contraction of a muscle be sustained at
just the right amplitude in order to isolate the firing of single muscle
fibers from the same unit. With patience on the part of the electro-
myographer, it is also possible to detect such pairs of fibers by
electrical stimulation of a nerve. Nerve conduction velocities and
distal latencies are normal unless there is a coincidental polyneu-
ropathy.

Edrophonium (Tensilon) and Neostigmine Tests Equally valu-
able to electrophysiologic testing are the edrophonium (Tensilon)
and neostigmine tests. These drugs are anticholinesterase inhibitors that prolong and exaggerate the effects of ACh in the synapse and thereby provide an increment in muscle power in the patient with myasthenia. The tests are performed in the following manner. After the measurement of strength in a cranial (usually the levator palpebrae or an extraocular muscle) or limb muscle (by dynamometry) or vital capacity, 1 mg (0.1 mL) of edrophonium is given intravenously; if this dose is tolerated and no definite improvement in strength occurs after 45 s, another 3 to 6 mg is injected. If there is no response after another 45 s, an additional 3 to 5 mg may be given over approximately 1 min. A total dose of 10 mg is rarely necessary. Most patients who respond do so after 3 to 5 mg have been administered. The mild muscarinic effects of edrophonium (nausea, vomiting, bowel activation, sweating, salivation) can be blocked by pretreatment with atropine 0.8 mg subcutaneously.

The clinical effect of improved ptosis, extraocular movements, oropharyngeal function, arm and shoulder abduction, or vital capacity persists for no more than 4 to 5 min. One caution: some patients deteriorate immediately but briefly after the edrophonium test as a result of an increase in pulmonary secretions. A positive test consists of visible (objective) improvement in muscle contrac-
tility, complete fusion of diplopia, or total resolution of fatigable ptosis. The report of subjective improvement alone is not dependable, complete fusion of diplopia, or total resolution of fatigable ptosis. The report of subjective improvement alone is not depend-
able, and one must be distrustful of equivocal test results, which may occur with ocular palsies due to tumors, thyroid disease, Guillain-Barré syndrome (GBS), progressive supranuclear palsy, or carotid aneurysms (pseudo-ocular myasthenia). The use of the edro-
phonium test in the diagnosis of so-called cholinergic crisis is discussed further on.

The use of neostigmine is sometimes preferable to edropho-
nium because the longer duration of its effect allows more delib-
erate and repeated testing of muscle function. Neostigmine meth-
ylsulfate is injected intramuscularly in a dose of 1.5 mg. As with the edrophonium test, atropine sulfate (0.8 mg) should be given several minutes in advance to counteract muscarinic effects. (Less preferably, neostigmine may be given intravenously in a dose of 0.5 mg, but its effect is brief.) After intramuscular injection, ob-
jective and subjective improvement occurs within 10 to 15 min, reaches its peak at 20 min, and lasts up to 1 h, allowing for careful verification of the neurologic improvement. A trial of oral prostig-
mine, 15 mg every 4 h during the day, is sometimes recommended in doubtful cases, but we have been misled more often than helped by it. A negative test with an anticholinesterase does not exclude myasthenia gravis but is a strong point against the diagnosis. In a small number of patients who later prove to have myasthenia gravis, the edrophonium and neostigmine tests (and EMG and AChR antibody measurements) may be entirely normal during the first episode or even after several episodes of ocular myasthenia. Only later, for inexplicable reasons, do these tests become positive. Finally, it should be noted that the anticholinesterase-inhibiting drugs carry a rare risk of ventricular fibrillation and cardiac arrest, so that testing should be carried out preferably where emergency support is accessible.

**Measurement of Receptor Antibodies in Blood** As stated earlier, the detection of *anti-AChR antibodies* provides a sensitive and highly specific test for the diagnosis of myasthenia. The radioim-
munoassay method of detection has been the most accurate and widely used. Serum antibody against AChR can be found in 80 to 90 percent of patients with generalized myasthenia gravis and about 60 percent of those whose symptoms are restricted to the ocular muscles (Vincent and Newsom-Davis). For the most part, adults with myasthenia whose sera are persistently negative for AChR antibodies do not differ clinically or electromyographically from those with antibodies, with the exception noted below. Persistently negative AChR antibody tests are more frequently found in patients with ocular myasthenia than in patients with generalized weakness. Patients with a thymoma and severe generalized myasthenia are practically always seropositive. Interestingly, the antibody titers may remain elevated during clinical remissions.

Some instances of “seronegative” disease are due to antibody production against unusual epitopes that are located on or near the AChR; their detection requires a special panel of tests. Recently, the majority of such cases have been ascribed to IgG antibodies directed against a muscle-specific kinase (MuSK). This enzyme plays a role in supporting the normal structure of the postsynaptic membrane and in the arrangement of AChR, but its main function may be in developmental synaptic differentiation. Scuderi and colleagues and others have proposed that patients with MuSK antibody, mostly women, have a special clinical syndrome of prominent oculobulbar weakness, often with persistently severe disease and respiratory crises (see also Evoli et al). Others have reported the opposite, a pattern of mainly neck and proximal weakness that simulates a classical myopathy.

Also of interest, but not used in routine diagnosis, is the pres-
ence of antibodies directed against striated muscle in almost half of myasthenic patients and an even higher incidence (stated to be 85 percent) in patients who also have a thymoma.

Each of the commonly used diagnostic tests proves to be about equally reliable. Kelly and coworkers obtained positive results with single-muscle-fiber recording in 79 percent, with the antireceptor antibody test in 71 percent, and with the edrophonium test in 81 percent. Combined, they confirmed the diagnosis in 95 percent of clinically suspected cases. Presumably, had the anti-MuSK receptor antibody test been available, the sensitivity of serologic diagnosis would have been higher.

In keeping with the observation of some myasthenic patients that their weakness improves in the cold, a test has been devised in which an ice pack is placed over a ptotic eyelid for 2 min or to the limit of the patient’s tolerance. Sethi and colleagues found that ptosis was diminished in 8 of 10 patients. We have been unsuccess-
ful in demonstrating this effect consistently, but it may be a useful adjunctive test.

Other diagnostic tests performed routinely in essentially all patients thought to have myasthenia gravis include CT of the chest (for the detection of thymic enlargement or thymoma), tests of thyroid function for reasons discussed further on, and, in cases of uncertain diagnosis, magnetic resonance imaging of the cranium and orbits to exclude compressive and inflammatory lesions of the cranial nerves and ocular muscles.

**Special Diagnostic Problems** We have encountered or been dis-
tracted by the following clinical problems in myasthenia:

1. *The concurrence of myasthenia gravis and thyrotoxicosis.* As indicated on page 1236, thyrotoxicosis may produce a char-
acteristic ocular myopathy. There is no certain evidence that thyrotoxicosis aggravates myasthenia gravis; some have even observed an inverse relationship between the severity of the two conditions. Hypothyroidism, however, does worsen my-
asthenia gravis. The ophthalmoplegia of thyrotoxicosis can usually be distinguished by the presence of an associated ex-
ophthalmos (early in the disease, exophthalmos may be absent), lack of ptosis, and the lack of definitive response to neostigmine. Polymyositis and inclusion body myopathy are differentiated from myasthenia by lack of involvement of extraocular muscles, but they may affect oropharyngeal muscles as does myasthenia. Finding the signs of these diseases in combination with those of myasthenia indicates a concurrence of two independent autoimmune diseases.

2. The neuroastic or depressed patient who complains of weakness when actually referring to fatigability. There is no ptosis, strabismus, or dysphagia, though a neurotic individual may complain of diplopia (usually of momentary duration when drowsy) and also of tightness in the throat (globus hystericus). A number of such patients claim improvement with neostigmine, but objective weakness and reversal thereof is always uncertain. Conversely, myasthenia is as often mistaken for hysteria or other emotional illness, mainly because the physician is unfamiliar with myasthenia (or with hysteria) and has been overly impressed with the precipitation of the illness by an emotional crisis. Fatigability is a feature of all of these conditions, but only in the psychiatric ones does it extend to the sphere of mental endurance. Moreover, those with myasthenia do not usually complain of fatigue, meaning of the body and mind, whereas these are frequent complaints in psychiatric conditions. A similar problem that has arisen frequently on our services pertains to judging breathlessness due to anxiety or cardiopulmonary disease in a patient with presumed myasthenia. Careful appraisal of the breathing pattern and determination of the vital capacity and more accurate spirometric measurements are helpful here.

3. Progressive external ophthalmoplegia and other restricted myopathies, including the congenital myasthenic states. These may be mistaken for long-established myasthenia gravis. It should be emphasized that the extraocular muscles and levator palpebrae may be permanently damaged by myasthenia and cease to respond to neostigmine. Another possibility is that restricted ocular myasthenia may not respond to anticholinesterase drugs from the beginning and the diagnosis of myasthenia is erroneously excluded. One must then turn to other muscles for clinical and electromyographic and serologic confirmation of the diagnosis.

4. Myasthenia with dysarthria and dysphagia, but without ptosis or obvious strabismus. These may be mistaken for multiple sclerosis, polymyositis, inclusion body myopathy, stroke, motor neuron disease, or some other neurologic disease. Testing with an anticholinesterase inhibitor, single-fiber recording, and measurement of antibodies usually clarifies the matter.

5. The initial manifestations of botulism—blurred vision, diplopia, ptosis, strabismus, and ophthalmoparesis—may be mistaken for myasthenia gravis of acute onset. In botulism, however, the pupils are usually large and unreactive, and the eye movements in myasthenia simulate an internuclear ophthalmoplegia. Ocular palsies, as may occur in nemaline polymyopathy, oculopharyngeal dystrophy, and thyrotoxic ophthalmic disease, come on too slowly in most cases to be confused with myasthenia gravis. On occasion, the eye movements in myasthenia simulate an internuclear ophthalmoplegia or other central appearing sign, even to the extent of including nystagmus in an abducting eye.

**Treatment** The treatment of this disease involves the careful use of two groups of drugs—anticholinesterases and immunosuppressants—thymectomy, and, in special circumstances, plasma exchange and intravenous immune globulin.

**Anticholinesterase Drugs** The two drugs that have given the best results in ameliorating myasthenic weakness are neostigmine (Prostigmin) and pyridostigmine (Mestinon), the latter being preferred by most clinicians and patients. The usual dose of pyridostigmine is 30 to 90 mg given every 6 h (typically a 60-mg pill is tried first); the oral dose of neostigmine ranges from 7.5 to 45 mg given every 2 to 6 h. Delayed-action forms of both drugs are available but are given at bedtime mainly to patients who complain of weakness during the night or early morning hours. The dosage of these drugs and their frequency of administration vary considerably from patient to patient, but we agree with Drachman that the maximal useful dosage of pyridostigmine rarely exceeds 120 mg given every 3 h. The dose-equivalents of these various drugs are shown in Table 53-1.

For mild cases without thymic tumor, for patients in partial remission after thymectomy, and for purely ocular myasthenia, the use of anticholinesterase drugs may be the only form of therapy necessary for some period of time (ocular myasthenia often responds well to small doses of corticosteroids as noted further on). Although these drugs seldom relieve symptoms completely (the response of ocular symptoms is typically incomplete), most such patients are able to remain functional.

If the response to anticholinesterase drugs is poor and progressively larger doses are not relieving symptoms, there is always the danger of a so-called cholinergic crisis. In our own experience with more than 60 patients of severe myasthenia in an intensive care unit, we have been persuaded of the occurrence of a cholinergic crisis only rarely. This consists of a relatively rapid increase in muscular weakness, usually coupled with the adverse muscarinic effects of the anticholinesterase drug (nausea, vomiting, pallor, sweating, salivation, bronchorrhea, colic, diarrhea, miosis, bradycardia). An impending cholinergic effect is betrayed by constriction of pupils. If the blood pressure falls as a result of bradycardia, 0.6 mg atropine sulfate should be given slowly by the intravenous route. Edrophonium may be used to determine whether weakness is due to an excess of anticholinesterase medications. However, this test has been misleading and undoubtedly has contributed to an overestimation of the frequency and importance of the cholinergic crisis. Infection or the natural course of the disease (“myasthenic crisis” as discussed later) has been a far more common cause of acutely worsening weakness and respiratory failure.

**Corticosteroids** For the patient with myasthenia with moderate to severe generalized weakness who is responding inadequately to anticholinesterase drugs, the long-term administration of corticosteroids is the most consistently effective form of treatment as described in a large series of patients by Pascuzzi et al. Small doses of corticosteroids (15 to 25 mg prednisone daily) alone or in combination with azathioprine (see later) are also often adequate to control ocular myasthenia. However, one must be prepared to contend with the side effects of long-term corticosteroid therapy, and we hesitate to undertake such a program in children or patients with severe diabetes or other diseases that are likely to be aggravated.

The usual form of corticosteroid therapy is prednisone (or corresponding doses of prednisolone), beginning with 15 to 20 mg/day and increasing the dose gradually until a satisfactory clinical response is obtained, or until a daily dose of 50 to 60 mg is reached. With higher doses or more rapid elevations of the doses, worsening in the first week is common, and hospitalization and careful observation for respiratory difficulty is advisable. Improvement after the initiation of corticosteroids occurs slowly over a few weeks. Once the maximal effect from prednisone has been attained, the dosage can be reduced gradually over months to the lowest point at which it is still effective. The usual practice has been to then institute an alternate-day schedule, which diminishes the side effects. Our patients have done better with a modest difference in dose from one day to the next, rather than omitting a dose entirely on alternate days. Potassium supplements and antacids should be prescribed liberally if needed, as with any chronic corticosteroid regime. At the outset of steroid therapy, anticholinesterase drugs are given simultaneously; as the patient improves, the dosage of the latter may be adjusted downward.

**Azathioprine (Imuran) and Other Immunosuppressive Drugs**

Azathioprine is a useful adjunct to steroids and can be effective alone in patients who cannot tolerate or fail to respond to prednisone. It has been possible to manage the disease reasonably well in a few patients with azathioprine alone. Treatment begins with 50 mg (1 tablet) twice daily for a few days; if this is tolerated, the dosage is raised to 2 to 3 mg/kg per day (150 to 250 mg daily). The number of positive responses is much the same as with prednisone. However, improvement occurs much more slowly with azathioprine, and a significant response may not be evident for many months to a year (Witte et al). Liver function tests and blood cell counts should be checked regularly. The Myasthenia Gravis Clinical Study Group found that the most severe forms of the disease, particularly those resistant to prednisone or azathioprine alone, benefit from the combination of the two medications. Many neurologists, including the present authors, begin by prescribing both medications early in the illness with the plan of reducing the corticosteroid dose in the third or fourth month.

**Mycophenolate (CellCept)** is currently being used as an adjunct to corticosteroids and has been beneficial in several small trials. The clinical improvement suggested by these studies has generally occurred sooner than it does with azathioprine (Meriggioli and colleagues). Diarrhea was the main adverse effect. Our initial impression is that mycophenolate may be preferable to most of the adjunctive medications and, in some milder cases, may be effective alone.

**Cyclophosphamide**, administered in intravenous pulses, has been used by De Feo and coworkers; they were able to remove 5 of their 12 patients from steroids but the appropriate use of this potent agent is not clear and we have resorted to it infrequently. Drachman and colleagues and others describe a regimen of high-dose cyclophosphamide (50 mg/kg/d for 4 consecutive days) followed by granulocyte-stimulating factor to “reboot” the immune system in refractory cases. This approach has risks but may be justified if all other measures have failed in severe instances of the disease. Liver function and white blood cell count should be monitored regularly. The clinical effects of the immunosuppressive agent cyclosporine are much like those of azathioprine but become evident more rapidly, in a matter of a month or two (Tindall et al). It is given in two divided doses daily, to a total of about 6 mg/kg but not often used currently because of serious side effects (hypertension, nephrotoxicity) and its high cost. Because of the success of alternative regimens, we have had occasion over the years to use cyclosporine only once for myasthenia.

**Plasma Exchange and Intravenous Immune Globulin** For severe myasthenia that is refractory to treatment with anticholinesterase drugs and prednisone, or during an acute worsening, one must resort to other measures. Striking temporary remissions (2 to 8 weeks) may be obtained by the use of plasma exchange. This form of treatment may be lifesaving during a myasthenic crisis, as noted later. It is also useful before and after thymectomy and at the start of immunosuppressive drug therapy. The number and volume of exchanges required in these circumstances is somewhat arbitrary, but they tend to be less than those required for GBS; several exchanges of 2 to 3.5 L each (totaling approximately 125 mL/kg), performed over a week, usually suffice. The removed plasma is replaced with albumin and saline. It has been estimated that a 2-L exchange will remove 80 percent of circulating antibodies and that this will be reflected in reduced AChr antibody levels in 3 to 5 days. However, there is only an approximate correlation between a reduction in the titer of anti-AChr antibody and the degree of clinical improvement. In a crisis requiring plasma exchanges and mechanical ventilation, it has been our practice to discontinue or curtail the use of anticholinesterase drugs and resume them as the patient is being weaned from the ventilator. Also, it may be that sensitivity...
to these drugs may be enhanced in the hours after an exchange, so that their dosages must be adjusted accordingly. Plasma exchange is also helpful in limiting the aforementioned weakness that is often induced by the institution of high-dose corticosteroids.

A small number of patients respond so well to plasma exchange and find the side effects of steroids so intolerable that they choose to be maintained with two to three exchanges every several weeks or months. Immunoabsorption, a technique similar to plasma exchange that removes antibodies and immune complexes by running blood over a tryptophan column, is less cumbersome than conventional plasma exchange and has been effective, but experience with this procedure is limited.

Intravenous immune globulin is similarly useful in the short-term control of acutely worsening myasthenia. The usual dose is 2 g/kg given in divided doses over 3 to 5 days. Several small series suggest that the effect is equivalent to a series of plasma exchanges. However, neither plasma exchange nor immune globulin has been subjected to systematic study or comparison, and it should be emphasized that while these measures are invaluable in deteriorated patients or those in crisis, they offer only short-term benefit and are not used regularly in the treatment of most patients.

Thymectomy This operation, first introduced by Blalock, is considered an appropriate procedure in practically all patients with uncomplicated myasthenia gravis between puberty and 55 years of age. The surgery is performed electively and not during an acute deterioration of myasthenia. The remission rate after thymectomy is approximately 35 percent provided that the procedure is done in the first year or two after onset of the disease, and another 50 percent will improve to some extent (Buckingham et al). The remission rate is progressively lower but not negligible if the operation is postponed beyond this time. In patients with myasthenia restricted to the ocular muscles for a year or longer, the prognosis is so good that thymectomy is unnecessary. The response to thymectomy is usually not evident for several months and is maximal by 3 years. In favorably responding cases, levels of circulating receptor antibody are reduced or disappear entirely. If possible, thymectomy should be postponed until puberty because of the importance of the gland in the development of the immune system, but juvenile myasthenia is also quite responsive. The results are not as predictable in patients who harbor a thymoma.

A suprasternal approach for removal of the gland has been developed and results in less postoperative pain and morbidity than occurs with a transternal thoracotomy, but the transternal operation is preferable because it assures a more complete removal of thymic tissue. Thymectomy is best performed in a hospital where there is close collaboration between the thoracic surgeon and the neurologist. If the patient is very weak preoperatively, a course of plasma exchange or immune globulin may be tried preceding the surgical procedure. Large “stress doses” of corticosteroids seem not to be necessary in most patients who have been taking these medications chronically. After operation, respiratory assistance must be available. Neostigmine, intramuscularly, may be given every 3 to 6 h postoperatively. Usually the dose requirement is about 75 percent of that taken before surgery. As improvement occurs, oral medications are resumed since remission is not anticipated for many months.

The benefit of thymectomy in children has already been described under “Clinical Manifestations.” Thymectomy is also a safe and effective treatment in elderly patients with myasthenia. In 12 such individuals, Olanow and associates reported complete remission in 9 and clinical improvement in the remainder. But generally, the improvement in older patients is less convincing than it is in the younger group, in part because the thymus is atrophic. Nonetheless, some of our patients over age 60 have benefited.

Removal of the thymus gland is also indicated in practically all patients in whom thymoma is detected by CT scanning of the chest. The tumor can be locally invasive but rarely metastasizes. The operative approach is through the anterior thorax, with adequate exposure to remove all the tumor tissue. If the tumor cannot be removed completely, the remaining tissue should be treated with focused radiation. Local spread and lymph node invasion has been treated with combinations of chemotherapy including cisplatin. Park and colleagues have concluded from a large retrospective study of metastatic cases that chemotherapy offers some benefit in terms of survival, but this remains a controversial issue.

**Myasthenic Crisis** A rapid and severe deterioration of the myasthenia itself, termed myasthenic crisis, can bring the patient to the brink of respiratory failure and quadriplegia in a matter of hours. A respiratory infection or excessive use of sedative medications or drugs with a potential for blocking neuromuscular transmission may precede the myasthenic crisis. We have encountered numerous cases in which oropharyngeal weakness has led to aspiration pneumonia, which, in turn, precipitated a crisis. Just as often, a precipitating event is not evident. Rarely, a respiratory arrest is the first manifestation of crisis. Such events may occur at any time after the diagnosis of myasthenia, but about half of them are evident within 12 to 18 months. In an experience with 53 patients in myasthenic crisis at the Columbia-Presbyterian Medical Center, infection, usually pneumonia, was the most frequent precipitating event, but no cause could be determined in almost one-third (Thomas et al).

Incipient respiratory failure is usually marked by a reduction of vital capacity, often accompanied by restlessness, anxiety, dia- phoresis, or tremor. Once the diaphragm fails, movements of the chest wall and abdomen become paradoxical (the abdomen moves inward during inspiration) or there may be shallow excursions of the chest, alternating with paradoxical movements. In an emergency, after clearing of the airway, such a patient can be supported briefly by a tight-fitting face mask and manual bag (Ambu) breathing. The chest wall will be found to be very compliant as a result of muscular weakness.

**Treatment of Myasthenic Crisis** Management of the crisis entails timely and careful intubation followed by mechanical ventilation in a critical care unit that is equipped to attend to the medical and neurologic needs of such patients. Respiratory failure in a few patients can be managed by the use of bilevel positive airway pressure (BiPAP) according to Rabinstein and Wijdicks, but this has not been consistently effective in avoiding endotracheal intubation in our experience. One must cope with both the oropharyngeal weakness that endangers the airway and the diaphragmatic weakness. Anticholinergic drugs, which exaggerate secretions, are best withdrawn at the time of intubation. The use of plasma exchange as described earlier appears to hasten improvement and weaning from the ventilator. Intravenous gamma globulin may be a useful alternative but has not been studied extensively. Some of our colleagues have used high-dose corticosteroid infusions, but this measure has not been particularly successful in our unit and, in the short run, carries the risk of inducing worsening of the weakness (Panegyres et al). Patients may respond to plasma exchange or immunoglobulin infusions in 1 or 2 days, but more often a week or more is required for recovery. It is generally best to wait 2 or 3 weeks before committing a patient to tracheostomy.
When weaning from the ventilator is anticipated, anticholinesterase agents are reintroduced slowly, and treatment with corticosteroids can be instituted if necessary. Oral doses of 60 mg pyridostigmine or 15 mg neostigmine are roughly equivalent to 0.5 to 1 mg neostigmine intravenously and 1.5 to 2 mg intramuscularly, as noted in Table 53-1. The management of the critically ill patient with myasthenia has been reviewed in the monograph by Ropper and colleagues.

Most patients with myasthenic crisis will take several weeks to recover, and a few of our patients have remained ventilator-dependent for months. In the extensive experience from Columbia-Presbyterian, half of patients could be safely extubated within 2 weeks and three-quarters by a month (Thomas et al). There were 7 deaths among 53 patients, reflecting the gravity of this syndrome even in the modern era of intensive care. Atelectasis, severe anemia, congestive heart failure, and clostridial diarrhea (associated with antibiotic use) portend a prolonged period of generalized weakness and intubation. From time to time one encounters a patient in whom respiration and ambulation do not improve for many months after a myasthenic crisis. In our experience, these have been middle-aged or older patients, usually women, in whom an element of hyperthyroidism or hypothyroidism may have been operative. They become wasted as the proximal limb and axial muscles, including the diaphragm, fail to recover their power, even though the ocular and oropharyngeal muscles improve. The role of corticosteroids in producing a concomitant proximal myopathy is a frequent question that can be solved by careful EMG examination.

The only recourse in cases of long-standing and severe myasthenia is to continue an average dose of corticosteroids and anticholinesterase medications with intermittent trials of immune globulin or plasma exchanges. This is also a situation in which high-dose cyclophosphamide followed by granulocyte-stimulating factor as mentioned earlier may result in slow improvement.

Management of Anesthesia and Pregnancy These represent special problems. Surgical procedures of any type are often sufficiently stressful to produce decompensation of the disease. If the patient is unable to take medications orally, anticholinesterase agents may be given intramuscularly (one-third of the oral dose of pyridostigmine and one-tenth the oral dose of neostigmine). If corticosteroids were being used, they may be continued and the dose generally left unchanged; large “stress” doses are generally not necessary. Neuromuscular blocking agents of the noncompetitive type may have a very prolonged effect and should be avoided as part of the anesthetic regimen. If they are necessary for some reason, a period of mechanical ventilation should be anticipated. In contrast, the dose of succinylcholine (which is not recommended) required to produce muscle relaxation may be larger than usual. Any drug, the use of which is contemplated in anesthetic and postsurgical management, should be checked against the list of agents that are capable of exaggerating myasthenic weakness (see later).

Pregnancy is usually uncomplicated in patients with myasthenia, but some women who are partially treated for myasthenia and have generalized weakness may have difficulty in assisting with vaginal delivery. However, the use of intravenous cholinesterase inhibitors is contraindicated because of the possibility of inducing uterine contractions, and cytotoxic drugs are generally avoided because of the potential for fetal abnormalities. Also, magnesium is not recommended for the treatment of eclampsia because of its neuromuscular blocking effects. Delivery usually proceeds normally, and breast-feeding is not thought to be a problem with regard to the transmission of AChR antibodies. The issues of neonatal myasthenia and of reduced intrauterine movements are considered later.

OTHER DISORDERS OF NEUROMUSCULAR TRANSMISSION (Table 53-2)

Considered here are several disorders of neuromuscular transmission characterized clinically by muscular weakness and fatigability but differing in mechanism from autoimmune myasthenia gravis. The Lambert-Eaton myasthenic syndrome, neonatal myasthenia, the congenital myasthenic syndromes, and the myasthenic syndromes induced by drugs and toxins are the main disorders in this group. Two additional important members—botulism and organophosphate poisoning—are described elsewhere in the book (pages 1032 and 1037, respectively).

The Myasthenic-Myopathic Syndrome of Lambert-Eaton (Lambert-Eaton Syndrome, LEMS)

This special form of myasthenia, observed most often in patients with oat-cell carcinoma of the lung, was first described by Lambert, Eaton, and Rooke in 1956 and further by Eaton and Lambert in 1957. Unlike classic myasthenia gravis, the muscles of the trunk, shoulder girdle, pelvic girdle, and lower extremities are the ones that become weak and fatigable. Characteristic EMG findings and poor response to anticholinesterase drugs also serve to differentiate it from myasthenia gravis. Often the first symptoms are difficulty in arising from a chair, climbing stairs, and walking; the shoulder muscles are affected later. While ptosis, diplopia, dysarthria, and dysphagia may occur, presentation with these symptoms is distinctly unusual. Increasing weakness after exertion stamps the condition as myasthenic, and in direct contrast to myasthenia gravis, there may be a temporary increase in muscle power during the first few contractions. The tendon reflexes are often diminished, but complete abolition of the reflexes should raise the question of an associated carcinomatous polyneuropathy. Fasciculations are not seen.

One of the most instructive reviews of this disease is that of O’Neill and colleagues; in 50 well-studied and fully developed cases they describe proximal leg weakness in all, arm weakness in 39, diplopia in 25, ptosis in 21, and dysarthria in 12. Other complaints were paresthesias, aching pain (suggesting arthritis), and a number of autonomic disturbances, such as dryness of the mouth, constipation, difficult micturition, and impotence. One should not be surprised to find other neurologic manifestations of neoplasia (e.g., polyneuropathy, polymyositis or dermatomyositis, multifocal leukoencephalopathy, cerebellar degeneration, as discussed in Chap. 31).

The onset of weakness is usually subacute and the course variable progressive. Males are affected more often than females (5:1). The myasthenia may precede discovery of the tumor by months or years. About 60 percent of cases are associated with small-cell lung cancer, but small numbers have also occurred with carcinoma of the breast, prostate, stomach, and rectum and with lymphomas. However, in about one-third of patients, no tumor is found; some of these cases are associated with other autoimmune diseases, but most are idiopathic. The condition may occur in chil-

AChE, acetylcholine esterase; AChR, acetylcholine receptor; MuSK, muscle-specific kinase; IVIG, intravenous immune globulin; DAP, diaminopyridine.

Dren, usually occurs with no relation to tumor. In the tumor cases, death usually occurs in a few months or years from the effect of the tumor itself; the idiopathic ones fluctuate over years.

As mentioned above, the response to neostigmine and pyridostigmine is poor or at least unpredictable. In contrast, d-tubocurarine, suxamethonium chloride, gallamine, and other muscle relaxants have a deleterious effect. Just as in myasthenia gravis, when given during anesthesia, they increase the weakness and even lead to fatality.

Conventional electrodiagnostic studies have shown no abnormality in the peripheral nerves. A single stimulus of nerve may evoke a low-amplitude muscle action potential (in contrast to myasthenia gravis, in which it is normal or nearly so), whereas at fast rates of stimulation (50 per second as shown in Fig. 45-5B) or with strong voluntary contraction (for 15 s or longer), there is a marked increase in the amplitude of action potentials (incrementing response). Single-fiber recordings show an increase in “jitter,” as in myasthenia gravis (page 1106).

In the Lambert-Eaton syndrome, there is an increased representation of HLA-B8 and -DR3 haplotypes, as occurs in other au-
to immune diseases. Elmquist and Lambert, from a series of studies of excised muscle, deduced that there is a defect in the release of ACh quanta from the presynaptic nerve terminals, akin to the effects of botulinum toxin, magnesium excess, and neomycin (see further on). The presynaptic vesicles themselves appear to be normal in electron micrographs. Also in contrast to myasthenia gravis, the extent of the receptor surface in this syndrome is actually increased (A. G. Engel).

The physiologic mechanism in Lambert-Eaton myasthenic syndrome is not fully delineated; however, a fundamental defect is a loss of voltage-sensitive calcium channels on the presynaptic motor nerve terminal. The calcium channels become cross-linked and aggregated by IgG autoantibodies, ultimately reducing the number of functioning channels (Fukunaga et al). In other words there are antibodies against a specific component of the presynaptic membrane that have the effect of reducing the presynaptic release of ACh, virtually the opposite of myasthenia gravis. A serologic test for these antibodies is available and is performed to confirm the diagnosis. Even in patients without detectable antibodies against voltage-gated calcium channels, passive transfer indicates the presence of a circulating factor with similar activity. Muscle biopsy is normal or shows only the same slight, nonspecific changes as in myasthenia gravis. The thymus is, of course, normal.

Recognition of the Lambert-Eaton syndrome should lead to a search for an occult tumor, particularly of the lung. A PET scan of the body may be useful in this regard, although CT of the lungs is usually adequate. If found, it should of course be treated; this alone may result in improvement in the neurologic syndrome. If none is found, the search should be repeated at regular intervals, since the tumors at first are small and may be inapparent even at autopsy.

**Treatment**  Most patients with this disease benefit from administration of 3,4-diaminopyridine (3,4-DAP), an agent that blocks potassium channels in the distal motor terminal, thus prolonging depolarizations and enhancing the release of ACh vesicles. The drug is given as 20 mg, up to 5 times a day either alone or in conjunction with pyridostigmine (Lundh et al). This has largely replaced the use of guanidine hydrochloride (20 to 30 mg/kg/day in divided doses), which had proved to be more effective in increasing strength than neostigmine or pyridostigmine but had significant hematologic and renal toxicity with long-term use. With regard to more long-term relief, numerous regimens have been tried and favored by different groups. Streib and Rothner were able to achieve long-term improvement with prednisone. Dau and Denys have claimed the best results in nontumor cases with repeated courses of plasmapheresis in combination with prednisone and azathioprine. Intravenous immune globulin has also been effective in a few reported cases. Bain and coworkers indicate that the benefit is due to reduction in calcium channel autoantibodies, but the precise mechanism whereby intravenous immune globulin produces this effect could not be established. Because of the unpredictable side effects of these drugs, many clinicians prefer alternate-day administration of prednisone and azathioprine—prednisone 25 to 60 mg/day, and azathioprine 2 to 3 mg/kg body weight daily—supplemented intermittently as needed by intravenous immune globulin. The response to treatment tends to be slow, over a period of months and sometimes up to a year. Some patients recover fully; in others, restoration of power is incomplete.

**Diagnosis**  A syndrome of symmetrical weakness and fatigability of proximal muscles—coupled with dry mouth, sphincter distur-

**Neonatal Myasthenia Gravis**

An estimated 12 to 20 percent of babies born to mothers with myasthenia show transient signs of myasthenia (hypotonia, weak cry and suck). This transitory phenomenon is apparent at birth and has a mean duration of about 2 to 5 weeks; recovery is usually complete within 2 months of birth (rarely longer), without later relapse. Uncommonly, the mother with myasthenia reports reduced intrauterine movements, suggesting a dangerous degree of myasthenia in the fetus. A few of these children will be born with arthrogryposis, the result of a sustained period of intrauterine immobility, and this complication then tends to recur in subsequent births.

It has long been assumed that neonatal myasthenia is due to the passive transplacental transfer of anti-AChR antibodies. This explanation is not entirely satisfactory, insofar as maternal AChR antibodies are transferred from mother to fetus in all AChR antibody–positive pregnancies and the incidence and severity of the neonatal myasthenia gravis does not correlate with the severity or duration of the mother’s illness or with the serum level of the maternal AChR antibody. In fact, neonatal myasthenia may occur when the mother is in remission.

Administration of plasma exchange and anticholinesterase drugs to the infant may be useful in hastening recovery from neonatal myasthenia.

**Congenital Myasthenic Syndromes**

(See Table 53-2)

Sporadically in the medical literature, there have appeared reports of a benign congenital myopathy in which myasthenic features could be recognized in the neonatal period or soon thereafter. The affected infants had been born to mothers who did not have myasthenia and were in the past described under headings such as “Myasthenia Gravis in the Newborn” and “Familial Infantile Myasthenia” (Greer and Schotland; Robertson et al) to distinguish the condition from passively transmitted neonatal myasthenia.

In the 1970s and 1980s, after the autoimmune basis of myasthenia gravis was established and its morphologic and physiologic features defined, the differences between this disease and the familial infantile forms became evident. Since then, at least eight distinct and rare congenital myasthenic syndromes have been delineated on the basis of their electrophysiologic and ultrastructural features, and a number of others have been partially characterized.

As indicated in Table 53-2, the congenital myasthenic syndromes are inherited defects in components of the presynaptic, synaptic, or postsynaptic junctional apparatus. Broadly speaking, the defects involve resynthesis or packaging of ACh or a paucity of synaptic vesicles (presynaptic); a deficiency of end-plate ACh esterase (synaptic); or kinetic abnormalities in the AChR channels, or AChR deficiency (postsynaptic). It has been estimated that in three-fourths of the cases the defect is postsynaptic.
Clinically, these disorders are distinguished by neonatal onset, fluctuating and sometimes progressive weakness that may be quite severe, sometimes pronounced muscle hypotrophy, persistent ptosis, and seronegativity for anti-AChR and anti-MuSK antibodies. Moreover, heritability (typically autosomal recessively) is suggested by familial occurrence of the disorders among siblings. In the neonate, the most important clue to the disease is an increase in ptosis and in bulbar and respiratory weakness with crying. Later in infancy these symptoms, as well as fluctuating ocular palsies and abnormal fatigability, are brought out by other types of sustained activity. Motor milestones may be delayed. In some cases, the myasthenic weakness and fatigability do not become evident until the second and third decades of life. The intravenous edrophonium test is inconsistently positive in a few forms of congenital myasthenia, but it usually is negative.

Both the fast channel syndrome and the slow channel syndrome are consequences of mutations in AChR subunits that respectively accelerate (fast channel) and slow (slow channel) the kinetics of gating of receptor channel (Crohex et al). Another well-characterized type of congenital myasthenia, usually causing arthrogryposis and recurrent apneic spells, but occasionally having a late onset (as late as 48 years), has been traced to mutations in the “rapsyn” gene. The rapsyn protein is believed to play a role in maintaining the integrity of the postsynaptic membrane (see Burke et al). Some of the congenital syndromes have special implications for therapy: drugs that are beneficial for one may be contraindicated in another. Deficiency of the enzyme required to synthesize and package ACh in vesicles (choline acetyl-transferase) causes a congenital myopathy with episodes of stress-induced apnea. In another type, the synaptic vesicles form poorly and are reduced in number. Being largely presynaptic defects, both of these disorders respond to ACh-esterase (AChE) inhibitors. In comparison, children with congenital myasthenia due to deficiency of AChE deteriorate markedly if given AChE inhibitors. Three disorders affecting post-synaptic structures (the fast channel syndrome, AChR deficiency, and the myasthenic syndromes associated with deficiencies of rapsyn and plectin) also respond to AChE inhibition and 3,4-DAP, while both agents are hazardous in individuals with the slow channel syndrome.

The studies of A. G. Engel have systematically defined and classified these disorders in a series of extensive investigations of more than 100 cases. A detailed and current account of this work can be found in his chapter on the subject in his monograph Myasthenia Gravis and Myasthenic Disorders.

Myasthenic Weakness due to Antibiotics and Other Drugs and to Natural Environmental Toxins (See Chap. 43 and Table 53-2)

Many drugs may cause a myasthenic syndrome or a worsening of myasthenia gravis by their action on pre- or postsynaptic structures. In the case of a nonmyasthenic patient, this is most likely to happen in the presence of hepatic or renal disease that allows excessive accumulation of the causative agent. The myasthenic state in these conditions is acute and lasts hours or days, with full recovery provided that the patient does not succumb to respiratory failure. The ocular, facial, and bulbar muscles are involved, just as in native myasthenia, as well as other muscles. The treatment in all instances is to provide respiratory support, discontinue the offending drug, and attempt to reverse the block at the end plate by infusions of calcium gluconate, potassium supplements, and the administration of anticholinesterases along the lines suggested by Argov and Mastaglia.

There are more than 30 drugs in current clinical use (other than anesthetic agents) that may, under certain circumstances, interfere with neuromuscular transmission in otherwise normal individuals. Of these, the most important are the aminoglycoside and quinolone antibiotics. Myasthenic weakness has been reported with 18 different antibiotics but particularly neomycin, kanamycin (less so with gentamicin), colistin, streptomycin, polymyxin B, and certain tetracyclines (McQuillen et al; Pittinger et al). It has been shown that these drugs impair transmitter release by interfering with calcium-ion fluxes at nerve terminals. The fluorinated quinolones (fluoroquinolones) group, typified by ciprofloxacin, affect both pre- and postsynaptic activity. They are especially hazardous when given to patients with myasthenia, but they may be used if necessary in such patients who are already receiving ventilatory support. Also, several of the immunosuppressant drugs—adrenocorticotropic hormone (ACTH), prednisone, and possibly azathioprine—worsen myasthenia temporarily by depolarizing nerve terminals or impairing release of ACh.

Other drugs—such as anticholinesterase agents, particularly the insecticides and nerve gases—cause paralysis by binding to cholinesterase and blocking the hydrolysis of ACh. The end plate remains depolarized and is refractory to neural stimuli. The most notable of these are: (1) botulinum toxin, which binds to cholinergic motor endings, blocking quantal release of ACh; (2) black widow spider venom, which causes a massive release of ACh, resulting in muscular contraction and then paralysis from a lack of ACh; (3) d-tubocurarine, which binds to AChR; (4) suxamethonium and decamethonium, which also bind to AChR; (5) organophosphates, which bind irreversibly to AChE; and (6) malathion and parathion, which inhibit AChE. The actions of all these agents except for the organophosphate “nerve gases” are transitory.

The administration of d-penicillamine has also caused an unusual type of myasthenia. The weakness is typical in that rest increases strength—as do neostigmine and edrophonium—and the electrophysiologic findings are also the same. In such cases, Vincent and others found anti-AChR antibodies in the serum; hence, one must assume that this is a form of induced autoimmune myasthenia gravis. In these respects it differs from the weakness caused by aminoglycosides (see review by Swift). Rarely, typical autoimmune myasthenia gravis develops as part of a chronic graft-versus-host disease in long-term (2- to 3-year) survivors of allogeneic marrow transplants.

A large group of naturally occurring environmental neurotoxins are known to act at the neuromuscular junction and to induce muscle paralysis of a pattern like that of myasthenia gravis. Venoms of certain snakes, spiders, and ticks are common and well-known animal poisons, as are ciguatera and related toxins (from fish that have ingested certain dinoflagellates), curare (from plants), and Clostridium botulinum—all of which are discussed in other parts of this book (see especially Chap. 43). Poisoning by these natural neurotoxins constitutes an important public health hazard in many parts of the world but particularly in the tropics. This class of disorders of neuromuscular transmission has been reviewed by Senanayake and Roman.

CHAPTER 54
THE PERIODIC PARALYSES
AND HEREDITARY,
NONDYSTROPHIC MYOTONIAS
(ION CHANNEL DISORDERS)

This chapter considers a category of disorders that is characterized by disturbances of the electrical excitability of the skeletal muscle membrane. The main manifestations are episodes of generalized paralysis and myotonia. The myotonias have been historically categorized as a special group of muscle diseases unified by the clinical sign of myotonia and were aligned in some older classifications with the muscular dystrophies. This view was based on myotonia as it was understood in the classic form of myotonic dystrophy, a subject discussed in Chap. 50. Similarly, before fundamental knowledge of their mechanism was revealed, the periodic paralyses (better called episodic paralysis) were considered to be metabolic diseases of muscle. However, in the last decades, it has become evident that most diseases that feature prominent myotonia and the collection of processes that cause episodic muscular paralysis are neither degenerative nor dystrophic. Careful clinical and electrophysiologic studies show that myotonia is an elemental feature of many nondystrophic conditions, foremost among them, the hyperkalemic form of periodic paralysis and myotonia congenita. All these diseases are now known to be caused by mutations in genes that code for chloride, sodium, calcium, or potassium ion channels in the muscle fiber membrane, and they are referred to as ion channel diseases, or, colloquially, as “channelopathies.” Within this group there are also instances of muscle conditions that have no myotonia but only periodic paralysis.

Given that these are disorders of muscle membrane excitability, it is not surprising that the primary defects are in voltage-dependent ion channels. By analogy, it was anticipated that ion channelopathies would be implicated in two other categories of disease in which there is altered membrane excitability, namely the epilepsies and cardiac arrhythmias, and indeed this has proven to be the case (see discussion in Chap. 16 on the epilepsies). The biology of the ion channels and their disease-related mutations are reviewed by Ackerman and Clapham, by Hanna and colleagues, and by Cannon. Molecular studies, notably those of Rüdel, Lehmann-Horn, and Ricker and their associates, have identified the fundamental defects in the myotonia and episodic paralyses and clarified their relationships. In the process, several new forms of nondystrophic myotonia have been defined.

The main features of the ion channel diseases affecting muscle are summarized in Table 54-1 and the individual members of the group are described as follows.

CHLORIDE CHANNEL DISEASES
Myotonia Congenita (Thomsen Disease)

This is an uncommon disease of skeletal muscle that begins in early life and is characterized by myotonia, muscular hypertrophy, non-progressive course, and dominant inheritance. It is distinctly different from myotonic dystrophy, which is characterized by a progressive degeneration of muscle fibers and has a different genetic basis (see page 1221).

History The disorder was first brought to the attention of the medical profession in 1876 by Julius Thomsen, a Danish physician who himself suffered from the disease, as did 20 other members of his family over four generations. His designation of ataxia muscularis was not correct, but his description left no doubt as to the nature of the condition in that it featured “tonic cramps in voluntary muscles associated with an inherited psychical indisposition.” The latter aspect of the condition was not borne out by subsequent studies and is now thought to be his erroneous speculation as to causality. Strümpell in 1881 assigned the name myotonia congenita to the disease, and Westphal in 1883 referred to it as Thomsen disease. Erb provided the first description of its pathology and called attention to two additional unique features, muscular hyperexcitability and hypertrophy. In 1923, Nissen, Thomsen’s great-nephew, extended the original genealogy to 35 cases in seven generations. In 1948, Thomsen updated the subject in a monograph that is still a useful clinical reference.

Thomsen disease is caused by one of several inherited molecular defects in the voltage-dependent chloride channel gene (CLCN1), as first demonstrated by Jentsch and associates (see Koch). It is interesting that some mutations behave as dominant traits while others have either a dominant or recessive pattern of inheritance (see Table 54-1). The physiologic mechanism whereby these mutations alter ion fluxes across the muscle membrane and cause myotonia is described further on.

Clinical Features Myotonia, a tonic spasm of muscle after forceful voluntary contraction, stands as the cardinal feature of the disease. As emphasized on page 1104, this phenomenon reflects electrical hyperexcitability of the muscle membrane. It is most pronounced after a period of inactivity. Repeated contractions “wear it out,” so to speak, and the later movements in a series become more swift and effective. Rarely the converse is observed—where only the later movements of a series induce myotonia (myotonia paradoxa); but usually this is a feature of another condition, cold-induced paramyotonia congenita (see further on). Unlike cramp, the myotonic spasm is painless, but after prolonged activity, nocturnal myalgia—a pinching-aching sensation in the overactive muscles—may develop and prove distressing. Close observation reveals a softness of the muscles during rest, and the initial contraction appears not to be significantly slowed.

The disease is usually inherited as a dominant trait so that, most often, other members of the family have been affected. Its congenital nature may be evident even in the crib, where the infant’s eyes are noted to open slowly after it has been crying or sneezing, and its legs are conspicuously stiff as the child tries to

CHO, carbohydrates; +, mild; ++, moderate; ++++, severe.
take its first steps. In other cases, the myotonia becomes evident only later in the first or second decade. The muscles are generously proportioned and may become hypertrophied, but seldom to the degree observed in the recessive form of the disease described further on under “Generalized Myotonia.” Despite their muscular appearance, these patients are inept in athletic pursuits.

When severe, the myotonia tends to affect all skeletal muscles but is especially prominent in the lower limbs. Attempts to walk and run are sometimes impeded to the extent that the patient stumbles and falls. Other limb and trunk muscles are also thrown into spasm, as are those of the face and upper limbs. One of the characteristic features is grip myotonia in which the patient is unable to release a handshake and must slowly open the fingers one at a time. Occasionally a sudden noise or fright may cause generalized stiffness and falling. Small, gentle movements such as blinking or elicitation of a tendon reflex do not initiate myotonia, whereas strong closure of the eyelids, as in a sneeze, sets up a spasm that may prevent complete opening of the eyes for many seconds. Spasms of extraocular muscles occur in some instances, leading to strabismus. If the patient has not spoken for a time, there is sometimes a striking dysarthria. Arising at night, the patient cannot walk without first moving the legs for a few minutes. After a period of rest, the patient may have difficulty in arising from a chair or climbing stairs. Loosening of one set of muscles after a succession of contractions does not prevent the appearance of myotonia in another area, nor in the same ones if used in another pattern of movement. Smooth and cardiac muscles are not affected and intelligence is normal. Lacking also are the narrow face, frontal balding, cataracts, and endocrine changes typical of myotonic dystrophy (page 1221). Myotonia that is evident in infancy is far more likely to represent myotonia congenita than myotonic dystrophy, in which myotonia rarely has its onset in the first few years of life.

Myotonia can also be induced in most cases by tapping a muscle belly with a percussion hammer (percussion myotonia). Unlike the lump or ridge produced in hypothyroid or cachectic muscle (myoedema), the myotonic contraction involves an entire fasciculus or an entire muscle and, unlike the phenomenon of idiomuscular irritability (contraction of a fascicle in response to striking the muscle), it persists for several seconds. If tapped, the tongue shows a similar reaction. An electrical stimulus delivered to the motor point in a muscle induces a prolonged contraction (Erb’s myotonic reaction). In Thomsen disease, as in virtually all forms of myotonia, the stiffness is somewhat exaggerated in cold. On a cold day, affected individuals may have a prolonged grimace with closed eyes after a sneeze. We have encountered two brothers with this disorder who describe diving into a cool swimming pool on a hot summer day and having to lie nearly motionless at the bottom of the pool for several seconds until the muscle stiffness abated enough to allow them to swim to the top. Prominent cold-induced myotonia, however, is more characteristic of paramyotonia congenita (see later).

Biopsy reveals no abnormality other than enlargement of muscle fibers, and this change occurs only in hypertrophied muscles. As often happens in fibers of increased volume, central nucleation is somewhat more frequent than it is in normal muscle. The large fibers contain increased numbers of normally structured myofibrils. In well-fixed biopsy material examined under the electron microscope, Schroeder and Adams were unable to discern any significant morphologic changes. There are no changes in the peripheral or central nervous system.

Myotonia Levior This was the name applied by DeJong to a dominantly inherited form of myotonia congenita in which the symptoms are of milder expression and later onset than those of Thomsen disease. In two patients of a myotonia levior family, Lehmann-Horn and coworkers identified a mutation of the same chloride ion channel (CLCN1) that is implicated in Thomsen disease. Thus it appears that myotonia levior is simply a mild form of Thomsen disease.

Diagnosis In patients who complain of spasms, cramping, and stiffness, myotonia must be distinguished from several of the disorders described in Chap. 55—myokymia, persistent muscle activity and the cramp-fasciculation syndromes, periodic hyperkalemic paralysis, Schwartz-Jampel syndrome, pathologic cramp syndrome, contracture of phosphorylase or phosphoryluteine kinase deficiency, and perhaps most of all, “stiff-man” syndrome. In none of these disorders is there percussion myotonia or the typical electromyogram (EMG) abnormality of myotonic discharge. The only possible exception is the Schwartz-Jampel syndrome of hereditary stiffness combined with short stature and muscle hypertrophy discussed in the next chapter. The regional nature and spontaneous activity of dystonia only superficially resembles myotonia.

Some uncertainty may arise in those patients who later prove to have myotonic dystrophy when only myotonia is noted in early life. The myotonia in these cases is usually mild, and in several families that we have followed, some degree of weakness and the typical facies of myotonic dystrophy could be appreciated even in early childhood. In paramyotonia congenita (see further on), there is also myotonia of early onset, but again it tends to be mild, involving mainly the orbicularis oculi, levator palpebrae, and tongue; the diagnosis or paramyotonia is seldom in doubt because of the worsening with continued activity and prominent cold-induced episodes of paralysis.

In patients with very large muscles, one must consider not only myotonia congenita but also familial hyperdevelopment, hypothyroid polymyopathy, the Bruck-De Lange syndrome (congenital hypertrophy of muscles, mental retardation, and extrapyramidal movement disorder), and hypertrophic polymyopathy (hypertrophia muscularorum vera). [This last disease is of current interest because the protein (myostatin) and gene defect have recently been characterized.] Muscle hypertrophy is not, of course, a feature of myotonic dystrophy. The demonstration of myotonia by percussion and EMG study usually resolves the problem, although it should be noted that in exceptional cases of Thomsen disease, the persistence of contraction may be difficult to demonstrate. In hypothyroidism, the EMG may show bizarre high-frequency (pseudomyotonic) discharges (page 1105). However, true myotonia does not occur, myoedema is prominent, and—along with other signs of thyroid deficiency—there is slowing of contraction and relaxation of tendon reflexes not seen in myotonia congenita.

Treatment Quinidine sulfate, 0.3 to 0.6 g; procainamide, 250 to 500 mg qid; and mexiletine, 100 to 300 mg tid, are beneficial in relieving the myotonia. Phenytoin, 100 mg tid, has also been useful in some cases. The cardiac antiarrhythmic drug tocazide (1200 mg daily) has also proved effective, but it sometimes causes agranulocytosis and is no longer recommended.

Generalized Myotonia (Becker Disease)

This is a second form of myotonia congenita, inherited as an autosomal recessive trait. Like the dominant Thomsen form, it is
caused by an allelic mutation of the gene encoding the chloride ion channel of the muscle fiber membrane. The clinical features of the dominant and recessive types are similar except that myotonia in the recessive type does not become manifest until 10 to 14 years of age or even later and tends to be more severe than the myotonia of the dominant type. The myotonia appears first in the lower limbs and spreads to the trunk, arms, and face. Hypertrophy is invariably present. There may be an associated mild distal weakness and atrophy; this was found in the forearms in 28 percent of Becker’s 148 patients and in the sternocleidomastoids in 19 percent. Dorsiflexion of the feet was limited and fibrous contractures were common. Weakness may also be present in the proximal leg and arm muscles. The most troublesome aspect of the disease is the transient weakness that follows initial muscle contraction after a period of inactivity. Progression of the disease continues to about 30 years of age, and according to Sun and Streib, the course of the illness thereafter remains unchanged. In contrast to Thompsen disease, the creatine kinase (CK) may be elevated. Testicular atrophy, cardiac abnormalities, frontal baldness, and cataracts—the features that characterize myotonic dystrophy—are conspicuously absent.

DISEASES OF THE SODIUM CHANNEL

The main diseases in this category are hyperkalemic periodic paralysis and paramyotonia congenita. The derivative disorders normokalemic periodic paralysis, acetazolamide-responsive myotonia, myotonia fluctuans, and myotonia permanens are variants of hyperkalemic periodic paralysis. All of them are due to mutations in the gene encoding the alpha subunit of the sodium channel in skeletal muscle (SCN4A).

Hyperkalemic Periodic Paralysis

The essential features of this disease are episodic generalized weakness of fairly rapid onset and a rise in serum potassium during attacks. Weakness appearing after a period of rest that follows exercise is particularly characteristic. This type of periodic paralysis was first described and distinguished from the more common (hypokalemic) form by Tyler and colleagues in 1951. Five years later, Gamstorp described two additional families with this disorder and named it adynamia episodica hereditaria. As further examples were reported, it was noted that in many of them there were minor degrees of myotonia, which brought the condition into relation with paramyotonia congenita (see further on). Hyperkalemic periodic paralysis was associated with a defect in the alpha subunit of the sodium channel gene (Fontaine et al); confirmation that it was a sodium channel disorder followed shortly thereafter. It is now appreciated that there are distinct variants of hyperkalemic periodic paralysis that breed true. All are associated with membrane hyperexcitability because of imperfections in the process of sodium channel inactivation following membrane depolarization as discussed later.

Clinical Manifestations The pattern of inheritance is autosomal dominant. Onset is usually in infancy and childhood. Characteristically, the attacks of weakness occur before breakfast and later in the day, particularly when resting following exercise. In the latter case, the weakness appears after 20 to 30 min of becoming sedentary. The patient notes difficulty that begins in the legs, thighs, and lower back and spreads to the hands, forearms, and shoulders over minutes or more. Only in the severest attacks are the neck and cranial muscles involved. Respiratory muscles are usually spared. As the muscles become inexcitable, tendon reflexes are diminished or lost. Attacks usually last 15 to 60 min, and recovery can be hastened by mild exercise. After an attack, mild weakness may persist for a day or two. In severe cases, the attacks may occur every day; during late adolescence and the adult years, when the patient becomes more sedentary, the attacks may diminish and even cease entirely. In certain muscle groups, if myotonia coexists, it is difficult to separate the effects of paresis from those of myotonia.

During the attack of weakness, serum K rises, often but not always up to 5 to 6 mmol/L. This is associated with an increased amplitude of T waves in the electrocardiogram (ECG) and a fall in the serum Na level (due to entry of Na into muscle). With increased urinary excretion of K, the serum K falls and the attack terminates. Between attacks, serum K is usually normal or only slightly elevated.

The attacks of paralysis are alike in all clinical variants of the disease. Usually the presence of myotonia can only be detected electromyographically. In the paramyotonic form discussed below, the attacks are associated with paradoxical myotonia—that is, myotonia induced by exercise and also by cold.

The provocative test, undertaken when the patient is functioning normally, consists of the oral administration of 2 g of KCl in a sugar-free liquid repeated every 2 h for four doses, if that many are necessary to provoke an attack. The test is given in the fasting state, ideally just after exercise. The weakness typically has a latency of 1 to 2 h after the administration of K. The patient must be carefully monitored by ECG and frequent serum K estimations. The test should never be undertaken in the presence of an attack of weakness or reduced renal function or in those with diabetes requiring insulin.

The treatment of this syndrome is the same as that for paramyotonia congenita, described further on.

Normokalemic Periodic Paralysis This form of episodic paralysis resembles the hyperkalemic form in practically all respects except that serum potassium does not increase out of the normal range, even during the most severe attacks. However, some patients with normokalemic periodic paralysis are sensitive to potassium loading (Poskanzer and Kerr); other kindreds are not (Meyers et al). The disorder is also transmitted as an autosomal dominant trait, and the basic defect has proved to stem from the same mutation as that of hyperkalemic periodic paralysis of which it may be considered a variant.

Paramyotonia Congenita (Eulenburg Disease)

In this disease, attacks of periodic paralysis are associated with myotonia, which may be paradoxical in type—that is, developing during exercise and worsening as the exercise continues. In addition, a widespread myotonia, often coupled with weakness, is induced by exposure to cold. In some patients the myotonia can be elicited even in a warm environment. The weakness may be diffuse, as in hyperkalemic periodic paralysis, or limited to the part of the body that is cooled. As commented in the earlier section on hyperkalemic paralysis, cold exaggerates many types of myotonia to
some extent, but this property is most characteristic of paramyotonia and it is in this condition that cold-induced weakness persists for up to several hours once started, even after the body is rewarmed. Percussion myotonia can be evoked in the tongue and thenar eminence. According to Haass and colleagues, myotonia that is constantly present in a warm environment diminishes with repeated contraction, whereas myotonia induced by cold increases with repeated contraction (paradoxical myotonia).

Like hyperkalemic periodic paralysis, paramyotonia congenita is transmitted in an autosomal dominant manner, and both diseases have been linked to the same gene (SCN4A), which encodes the alpha subunit of the muscle membrane sodium channel; the two diseases are caused by allelic mutations.

Laboratory Findings In both hyperkalemic periodic paralysis and paramyotonia congenita, the serum K is usually above the normal range during bouts of weakness, but paralysis has been observed at levels of 5 meq/L or even lower. Each patient appears to have a critical level of serum K, which, if exceeded, will be associated with weakness. (This has led some authors to term the periodic paralysis as potassium dependent.) The administration of KCl, raising serum K to above 7 meq/L, a level that has no effect on normal individuals, invariably induces an attack. As mentioned earlier, the ECG must be monitored during such provocative testing. The EMG shows myotonic discharge in all muscles, even at normal temperatures. The CK may be elevated.

In vitro studies of muscle from patients with cold-induced stiffness and weakness have shown that as temperature is reduced, the muscle membrane is progressively depolarized to the point where the fibers are inexitable (Lehmann-Horn et al). A sodium channel blocker (tetrodotoxin) prevents the cold-induced depolarization. In patients with paramyotonia—but not in those with hyperkalemic periodic paralysis—Subramony and colleagues have observed a diminution of the compound muscle action potential in response to the cooling of muscle, settling the argument as to whether the two syndromes (hyperkalemic paralysis and paramyotonia) are the same or different.

Some patients with paramyotonia, like those with certain other forms of periodic paralysis, may in later life slowly develop a myopathy that causes persistent weakness. In some cases this is sufficiently severe that it mimics the pattern of late-onset limb girdle muscular dystrophy. However, in the case of paramyotonia there are relatively few histologic changes, primarily vacuoles in some of the muscle fibers and minimal evidence of myofiber degeneration.

Treatment Most patients with hyperkalemic periodic paralysis and its variants benefit from prophylactic use of the carbonic anhydrase inhibitor acetazolamide, 125 to 250 mg two or three times a day. Acetazolamide reduces the frequency of attacks and may provide some relief from myotonia. There are no controlled studies of acetazolamide in these disorders, but a rigorous trial of the related carbonic anhydrase inhibitor dichlophenamide demonstrated a reduced frequency of paralytic spells in both hyper- and hypokalemic forms of periodic paralysis (Tawil et al). In contrast, many attacks of primary hyperkalemic paralysis and of paramyotonia congenita are too infrequent, too brief, or too mild to require continuous treatment.

The continuous use of conventional diuretics such as hydrochlorothiazide (about 0.5 g daily), keeping the serum K below 5 meq/L, also prevents attacks but risks inducing dangerous degrees of hypokalemia. When the myotonia is more troublesome than the weakness, mexiletine 200 mg tid is perhaps the best alternative, since it prevents both cold- and exercise-induced myotonia, but it does not influence frequency of acute attacks. Some additional benefit may be gained by adding beta-adrenergic agonists such as albuterol or salbutamol. Some studies suggest that clenbuterol may have a direct effect in blocking the sodium channel, independent of its activation of adrenergic receptors. Procainamide or the lidocaine derivative tocanide, in doses of 400 to 1200 mg daily, are also useful for the myotonia (the last carries a small risk of agranulocytosis).

For the treatment of an acute and severe episoide, intravenous calcium gluconate (1 to 2 g) often restores power. If, after a few minutes, this treatment is unsuccessful, intravenous glucose or glucose and insulin and hydrochlorothiazide should be tried in order to reduce serum potassium concentration.

Other Sodium Channel Disorders Several other clinical presentations of hereditary periodic paralysis have been linked to mutations of the gene encoding the alpha subunit of the skeletal muscle sodium channel and probably represent variants of the disease just described. One of these, described by Ricker and colleagues, has been designated myotonia fluctuans, because muscle stiffness fluctuated in severity from day to day. In other respects the clinical features resembled those of myotonia congenita, including provocation of attacks of myotonia by exercise. The muscle stiffness was only slightly sensitive to cold but was markedly aggravated by the ingestion of potassium and, interestingly, never progressed to muscular weakness or paralysis. Myotonia permanens is the name given to a severe, persistent myotonia and marked hypertrophy of muscles, particularly of the neck and shoulders. The EMG discloses continuous muscle activity. This disease was discovered in the course of genotyping a patient who earlier had been reported by Spaans and associates as an example of “myogenic” Schwartz-Jampel syndrome, but it affects the same chloride channel as in hyperkalemic periodic paralysis.

Trudell and colleagues studied 14 patients from a large kindred with autosomal dominant myotonia, the main feature of which was periodic worsening of myotonia accompanied by muscle pain and stiffness, most severe in the face and hands. The symptoms were enhanced by cold (suggesting paramyotonia), and severe stiffness and palpable rigidity followed within 15 min of the ingestion of potassium. Neither of these measures provoked muscle weakness. Muscle biopsy disclosed a normal ratio of types 1, 2A, and 2B fibers, further distinguishing this disorder from typical myotonia congenita, where 2B fibers may be reduced in number. All patients in this family who were treated with the carbonic anhydrase inhibitor acetazolamide had a dramatic resolution of symptoms within 24 h—hence the name acetazolamide-responsive myotonia. This disorder has now been linked to the same molecular alteration of the sodium channel gene as occurs in hyperkalemic periodic paralysis (Ptáček et al).

Rosenfeld and coworkers have described yet another form of painful congenital myotonia attributable to a novel mutation in the sodium channel alpha-subunit gene (SCN4A). Affected members of this family experienced debilitating pain, particularly severe in the intercostal muscles. Also, the pain was resistant to treatment with acetazolamide and other antmyotonic drugs (mexiletine and tocainamide) and could not be provoked by ingestion of potassium-rich foods—differing in these ways from the patients described by Trudell and Ptáček and their associates.
Finally, in regard to disorders of the sodium channel, it should be mentioned that the marine toxins (ciguatoxin, tetrodotoxin, saxitoxin), discussed in Chap. 43, produce their effects on the peripheral and central nerves by blocking sodium channels, but they have little obvious effect on muscle function.

Pathophysiology of Myotonia and Hyperkalemic Periodic Paralysis

In both myotonia congenita and hyperkalemic paralysis, the absence of major morphologic changes and the prominence of the myotonic phenomenon in individual muscle fibers point to the existence of a physiologic aberration in the sarcolemma or some other part of the electrical conducting apparatus of the muscle fibers. This is consistent with the observation that myotonia persists after the administration of curare, thereby exonerating neural input as the source of myofiber hyperexcitability.

The electromyographic pattern of a myotonic muscle reveals highly characteristic discharges that persist following the cessation of voluntary contraction. The tension of the myotonic muscle fibers is slow to diminish as a result of these greatly prolonged trains of muscle action potentials (see Fig. 45-8). Some of these afterdischarge potentials are the size of fibrillations but others are as large as normal motor units. Thus myotonia can be distinguished electrophysiologically from contracture (e.g., that encountered in McArdle disease, in which the muscle is electrically silent). In classic experiments conducted in the 1940s, Denny-Brown and Foley, stimulating single muscle fibers directly, found that myotonic discharges could be elicited only by a volley of stimuli and not by a single stimulus. They also noted that the series of myotonic potentials progressively diminished in size. Percussion elicits myotonia by imparting a brief but relatively intense repetitive excitation of the muscle membrane.

The biophysical basis of myotonia is now well understood in terms of the functioning of chloride and sodium channels. The correspondence between mathematical models of the electrical properties of the muscle membrane and the clinical features of the myotonic and periodic paralyses is quite remarkable. During the normal action potential in all neural and muscular tissue, membrane depolarization is terminated by two events: the depolarization-induced inactivation of the sodium channel (which ends the inward sodium current) and the subsequent action of the outward potassium current. In muscle, the termination of an action potential requires an additional factor. Because of its large size, excitation of the muscle fiber involves depolarization that propagates not only along the cell surface but also radially into the center of the muscle cell through the transverse tubules (T tubules). The tubules are very narrow structures whose internal spaces are in continuity with the extracellular space. When the repolarizing outward potassium current is activated, potassium ions flood into the tubules from the muscle cytoplasm. By itself, this tubular K accumulation would cause imperfect inactivation of the channel and lead to aberrant and early reopenings. Repolarization is then incomplete, rendering the muscle cell more readily re-excited; it is this hyperexcitability that causes the myotonia of hyperkalemic periodic paralysis. The physiologic problem becomes self-reinforcing because, as the membrane fails to repolarize fully, its electrolytic inactivation becomes increasingly less effective. If this process is not aborted, the result is such excessive depolarization to a degree that the muscle cell ultimately becomes unexcitable—a state that corresponds to the paralytic phase of hyperkalemic periodic paralysis. These features are evident in hyperkalemic muscle in vitro (Cannon) and can be recapitulated in computer simulations. Presumably, over several hours, a variety of compensatory mechanisms [e.g., activation of Na-K adenosine triphosphatase (ATPase) pumps] restores the baseline excitability of the muscle membrane.

DISEASES OF THE CALCIUM CHANNEL

Hypokalemic Periodic Paralysis

This is the best-known form of periodic paralysis. The history of the disease is difficult to trace, but the first unmistakable account was probably that of Hartwig in 1874, followed by the accounts of Westphal (1885) and Oppenheim (1891). Goldflam (in 1895) first called attention to the remarkable vacuolization of the muscle fibers that is characteristic of the process. In 1937, Aitken and associates described the occurrence of low serum potassium during attacks of paralysis and reversal of the paralysis by the administration of potassium, thus setting the stage for subsequent differentiation of the hypokalemic forms of periodic paralysis. For English-speaking readers, Talbott’s monograph serves as the best historical review of the subject and includes all cases that had been reported prior to 1941; the more recent reviews by Layzer and by Lehmann-Horn and Engel and their associates bring the subject largely up to date.

The usual pattern of inheritance is autosomal dominant with reduced penetrance in women (male-to-female ratio of 3 or 4 to 1). Fontaine and Ptäček and their coworkers have localized the disease to chromosome 1q in a region containing the gene that encodes the alpha subunit of the calcium channel of skeletal muscle. The subunit, which is part of the dihydropyridine receptor complex, is located in the transverse tubular system. This region is believed to act both as a voltage sensor that controls calcium release from the sarcoplasmic reticulum, thus mediating muscle excitation-contraction coupling, and as a calcium-conducting pore. How the reduced calcium channel function relates to hypokalemic-induced attacks of muscle weakness is not known.

Clinical Manifestations In our experience, this disease has become clinically apparent after adolescence and has been much more severe in males. We note, however, that in Talbott’s review of 152 cases, there were 40 in which symptoms began before the 10th year of life and 92 before the 16th year. The typical attack comes on during the second half of the night or the early morning hours, after

de myotonia was confirmed in a mouse model by Jentsch and Steinmeyer and colleagues (see Koch et al), who subsequently also described the first human chloride channel (CLCN1) mutations.

As indicated, an essential event for normal repolarization of an excitable membrane is the rapid inactivation of the inward sodium current. This process of rapid, complete sodium channel inactivation is impaired by the sodium channel mutations implicated in hyperkalemic periodic paralysis. The sodium channel mutations cause imperfect inactivation of the channel and lead to aberrant and early reopenings. Repolarization is then incomplete, rendering the muscle cell more readily re-excited; it is this hyperexcitability that causes the myotonia of hyperkalemic periodic paralysis. The physiologic problem becomes self-reinforcing because, as the membrane fails to repolarize fully, its electrolytic inactivation becomes increasingly less effective. If this process is not aborted, the result is such excessive depolarization to a degree that the muscle cell ultimately becomes unexcitable—a state that corresponds to the paralytic phase of hyperkalemic periodic paralysis. These features are evident in hyperkalemic muscle in vitro (Cannon) and can be recapitulated in computer simulations. Presumably, over several hours, a variety of compensatory mechanisms [e.g., activation of Na-K adenosine triphosphatase (ATPase) pumps] restores the baseline excitability of the muscle membrane.

DISEASES OF THE CALCIUM CHANNEL

Hypokalemic Periodic Paralysis

This is the best-known form of periodic paralysis. The history of the disease is difficult to trace, but the first unmistakable account was probably that of Hartwig in 1874, followed by the accounts of Westphal (1885) and Oppenheim (1891). Goldflam (in 1895) first called attention to the remarkable vacuolization of the muscle fibers that is characteristic of the process. In 1937, Aitken and associates described the occurrence of low serum potassium during attacks of paralysis and reversal of the paralysis by the administration of potassium, thus setting the stage for subsequent differentiation of the hypokalemic forms of periodic paralysis. For English-speaking readers, Talbott’s monograph serves as the best historical review of the subject and includes all cases that had been reported prior to 1941; the more recent reviews by Layzer and by Lehmann-Horn and Engel and their associates bring the subject largely up to date.

The usual pattern of inheritance is autosomal dominant with reduced penetrance in women (male-to-female ratio of 3 or 4 to 1). Fontaine and Ptäček and their coworkers have localized the disease to chromosome 1q in a region containing the gene that encodes the alpha subunit of the calcium channel of skeletal muscle. The subunit, which is part of the dihydropyridine receptor complex, is located in the transverse tubular system. This region is believed to act both as a voltage sensor that controls calcium release from the sarcoplasmic reticulum, thus mediating muscle excitation-contraction coupling, and as a calcium-conducting pore. How the reduced calcium channel function relates to hypokalemic-induced attacks of muscle weakness is not known.

Clinical Manifestations In our experience, this disease has become clinically apparent after adolescence and has been much more severe in males. We note, however, that in Talbott’s review of 152 cases, there were 40 in which symptoms began before the 10th year of life and 92 before the 16th year. The typical attack comes on during the second half of the night or the early morning hours, after
a day of unusually strenuous exercise; a meal rich in carbohydrates favors its development. Excessive hunger or thirst, dry mouth, palpitation, sweating, diarrhea, nervousness, and a sense of weariness or fatigue are mentioned as prodromata but do not necessarily precede an attack. Usually the patient awakens to discover a mild or severe weakness of the limbs. However, diurnal attacks also occur, especially after a nap that follows a large meal. The attack evolves over minutes to several hours; at its peak, it may render the patient so helpless as to be unable to call for assistance. Once established, the weakness lasts a few hours if mild or several days if severe.

The distribution of the paralysis varies. Limbs are affected earlier and often more severely than trunk muscles, and proximal muscles are possibly more susceptible than distal ones. The legs are often weakened before the arms, but exceptionally the order is reversed. The muscles most likely to escape are those of the eyes, face, tongue, pharynx, larynx, diaphragm, and sphincters, but on occasion even these may be involved. When the attack is at its peak, tendon reflexes are reduced or abolished and cutaneous reflexes may also disappear. Sensation is preserved. As the attack subsides, strength generally returns first to the muscles that were last to be affected. Headache, exhaustion, diuresis, and occasionally diarrhea may follow the attack. Myotonia is not seen; indeed, clinical or EMG evidence of myotonia essentially excludes the diagnosis of hypokalemic periodic paralysis.

Attacks of paralysis tend to occur every few weeks and tend to lessen in frequency with advancing age. Rarely, death may occur from respiratory paralysis or derangements of the conducting system of the heart. Mainly, such fatal cases were reported in the era before modern intensive care.

Atypical forms include weakness of one limb or certain groups of muscles, bibrachial palsy (inability to lift one’s arms or to comb one’s hair), and transient weakness during accustomed activities. Earlier descriptions in the literature of daily brief attacks, some associated with exposure to cold or coupled with muscular hypertrophy or exophthalmic goiter, preceded recognition of the other types of periodic paralysis and cannot be evaluated. Some of our patients had a talipes deformity from early life. During middle adult life, a number of patients have developed a slowly progressive proximal myopathy, with vacuolated and degenerated fibers and myopathic action potentials, in some instances long after attacks of periodic paralysis had ceased.

Laboratory Findings The attacks are accompanied by reduction in serum K levels, as low as 1.8 meq/L, but usually at levels that would not be associated with muscle weakness in normal subjects. The fall in serum K is associated with little or no increase in urinary K excretion. Presumably, large quantities of K enter the muscle fibers during an attack, but this explanation may not be complete. Some episodes occur with near-normal levels of K, and weakness persists for a time after the serum level has been restored. The serum K levels return to normal during recovery. Although the shifts in K are of undoubted importance in the pathogenesis of muscle weakness, the marked sensitivity to small reductions of serum K suggests that other factors are also operative and that the fall in K may be a secondary phenomenon.

As in hyperkalemic paralysis, the muscular weakness in this disease is associated with a decrease in the amplitude, and eventual loss, of muscle action potentials and there is failure of excitation by supramaximal stimulation of peripheral nerve or by strong voluntary effort. A decline in strength precedes loss of motor unit potentials and the failure of propagation of action potentials over the surface of the fiber. The polarization potentials of muscle fibers measured by intracellular recordings are initially normal despite the failure of impulse propagation by the sarcolemma. One would expect the muscle fiber to be hyperpolarized as K moves into it, but it actually becomes depolarized. Rüdel and associates attribute the latter change to an increased Na conductance. The ECG changes also begin at levels of K that are slightly below normal (about 3 meq/L); they consist of prolonged PR, QRS, and QT intervals and flattening of T waves.

Diagnosis at a time when the patient is normal may be facilitated by provocative tests. With the patient carefully monitored, including the use of an ECG, the oral administration of 50 to 100 g of glucose or loading with 2 g of NaCl every hour for seven doses, followed by vigorous exercise, brings on an attack, which then can be terminated by 2 to 4 g of oral KCl (the opposite of what pertains in hyperkalemic periodic paralysis).

Pathologic Changes The nervous system is entirely normal. The muscle fibers are uniformly somewhat large, but the most striking change, particularly in the late degenerative phases of the disease, is vacuolization of the sarcoplasm. The myofibrils are separated by round or oval vacuoles containing clear fluid, presumably water, and a few PAS-positive granules. There are pathologic changes in myofibrils and mitochondria as well and focal increases in muscle glycogen. Isolated muscle fibers may undergo segmental degeneration. Electron microscopic studies have shown that the vacuoles arise as a result of proliferation and degeneration of membranous organelles within the sarcoplasmic reticulum and transverse tubules (A. G. Engel).

Treatment A low-sodium diet (160 meq/day), avoidance of large meals and exposure to cold, and acetazolamide 250 mg three times daily may be helpful in preventing attacks. That acetazolamide reduces attacks is somewhat surprising since it is kaluretic, but it may work through the production of acidosis; a few patients have worsened with the drug. Patients who are unresponsive to acetazolamide may be treated with the more potent carbonic anhydrase inhibitor, dichlorphenamide, 50 to 150 mg per day or with the potassium-sparing diuretics spironolactone or triamterene (both in doses of 25 to 100 mg/day) but caution must then be exercised with the simultaneous administration of oral potassium supplements. The daily administration of 5 to 10 g of KCl orally in an unsweetened aqueous solution prevents attacks in many patients, and apparently this program can be maintained indefinitely. If this approach fails, a low-carbohydrate, low-salt, high-K diet combined with a slow-release K preparation may be effective.

For an acute attack, 0.25 meq KCl/kg should be given orally or, if this is not tolerated, some other K salt may be tried. This dose may be insufficient, and if there is no improvement in 1 or 2 h, KCl may have to be given intravenously—0.05 to 0.1 meq/kg intravenously initially in a bolus at a safe rate, followed by 20 to 40 meq KCl in 5% mannitol, avoiding glucose or NaCl as the carrier solution. For the late progressive polymyopathy that follows many severe attacks of periodic paralysis, Dalakas and Engel report successful restoration of strength by the long-term administration of the carbonic anhydrase inhibitor dichlorphenamide. Regular exercise (not too strenuous) to keep the patient fit is desirable.

Secondary Kalemic Periodic Paralyses

In addition to the hereditary kalemic paralyses described earlier, transitory episodes of weakness are known to be associated with a number of acquired derangements of potassium metabolism.
Malignant Hyperthermia

This dramatic syndrome is observed during general anesthesia in susceptible individuals. It is characterized by rapidly rising body temperature, extreme muscular rigidity, and a high mortality rate. Since the original report by Denborough and Lovell in 1960, as larger experience was gained with this entity, it proved to be a metabolic polymyopathy inherited as a dominant trait, rendering the individual vulnerable to any potent volatile anesthetic agent, particularly halothane, and to the muscle relaxant succinylcholine. The fundamental cause in a large proportion of cases is an aberration in a component of the calcium channel. Malignant hyperthermia has been estimated to occur approximately once in the course of every 50,000 administrations of general anesthesia.

The full clinical picture is striking but anesthesiologists have become adept at detecting its earliest stages. As halothane or a similar inhalational anesthetic is induced or succinylcholine is given for muscular relaxation, the jaw muscles unexpectedly become tense rather than relaxed, and soon the rigidity extends to all of the muscles. Thereafter, the body temperature rises to 42°F or 43°C (5.5°C or 6.1°C) with tachypnea and tachycardia. Arterial CO₂ may exceed 100 mmHg, and blood pH may fall to 7.00 or below. There may be gross myoglobinuria, and serum CK often reaches extraordinarily high levels. Circulatory collapse and death may ensue in approximately 10 percent of cases, or the patient may survive with gradual recovery. In some cases there is the same sequence of events (increased temperature and acidosis) without muscular spasm. With the patient’s early death, the muscle may appear normal by light microscopy. In case of survival for several days, samples of muscle reveal scattered segmental necrosis and phagocytosis of sarcoplasm without inflammation. Regenerative activity is in progress. Multicores, which are characteristic of a particular congenital polymyopathy, may be found in the muscle of patients who have had such episodes.

Pathophysiology The pathogenesis of this reaction has been the subject of a number of investigations. During the rigor phase, oxygen consumption in muscle increases threefold and serum lactate, 15- to 20-fold. Muscle from most affected individuals is abnormally sensitive to caffeine, which induces contracture in vitro. It has been postulated that halothane acts in a manner similar to caffeine—that is, to release calcium from the sarcoplasmic reticulum and prevent its reaccumulation, thus interfering with relaxation of the muscle. There is a breed of pigs, inbred for muscular development, in which muscle spasm (true contracture) and hyperthermia follow the administration of anesthetic agents. These swine have an inherited defect in the ryanodine receptor, a protein component of the calcium channel of the sarcoplasm that is sensitive to both caffeine and ryanodine. However, one of several similar defects in ryanodine is found in somehow fewer than 20 percent of human beings. It is presumed that other yet unidentified allelic mutations of this receptor protein or another that controls the structure of the calcium channel account for the remainder of cases. The essential physiologic change is one of increased intracellular calcium. The cause of the high fever is not known; it is probably due to the muscle spasm, but an effect of the anesthetic on heat-regulating centers cannot be excluded.

Clues as to which patients are at risk for this condition come from several sources. Other members of the family may have collapsed or died during anesthesia. Some of the susceptible individuals exhibit certain myopathic and musculoskeletal abnormalities.

CHAPTER 55

DISORDERS OF MUSCLE CHARACTERIZED BY CRAMP, SPASM, PAIN, AND LOCALIZED MASSES

Quite apart from spasticity and rigidity, which are due to a disinhibition of spinal motor mechanisms, there are forms of muscular stiffness and spasm that can be traced to abnormalities of the lower motor neuron and its spinal inhibitory mechanisms or to the sarcoplemma of the muscle fiber and its intrinsic conducting apparatus. Thus, muscles may go into spasm because of an unstable depolarization of motor axons, which sends volleys of impulses across neuromuscular junctions—as occurs in myokymia, hypocalcemic tetany, and pseudohypoparathyroidism. In other states, discussed in the preceding chapter, the innervation of muscle may be normal but contraction persists despite attempts at relaxation (myotonia). Or, after one or a series of contractions, the muscle may be slow in decontracting, as occurs in paradoxical myotonia and hypothyroidism; in the contracture of McArdle phosphorylase deficiency and phosphofructokinase deficiency, muscle, once contracted, may lack the energy to relax.

Each of these conditions evokes the complaint of cramp or spasm, which is variably painful and interferes with free and effective voluntary activity. Each condition has its own identifying clinical and electromyographic (EMG) characteristics, and most of them respond favorably to therapy. A premium is therefore attached to the clinical differentiation of these phenomena.

Muscle Cramp

This subject has already been introduced in Chap. 48, where it was pointed out that everyone at some time or other experiences muscle cramps. Usually they occur during the night, after a day of unusually strenuous activity;less often they occur during the day, either during a period of relaxation or occasionally after a strong voluntary contraction or postural adjustment. A random restless or stretching movement will induce a hard contraction of a single muscle (most frequently of the foot or leg) that cannot be voluntarily relaxed. The muscle is visibly and palpably taut and painful, and the condition is readily distinguished from an illusory cramp, in which the sensation of cramp is experienced with little or no contraction of muscle. The latter phenomenon may occur in normal persons as well as in those with certain peripheral nerve diseases. Massage and vigorous stretch of the cramped muscle will cause the spasm to yield, though for a time the muscle remains excitable and subject to recurrent cramps. Visible fasciculations may precede and follow the cramp, indicating an excessive excitability of the terminal branches of motor neurons supplying the muscle. Sometimes the cramp is so strong that the muscle appears to have been injured; it remains sore to touch and painful upon use for a day or longer. Cramps of precordial chest muscles or diaphragm may arouse fear of heart or lung disease. In the EMG, the cramp is marked by bursts of high-frequency, high-voltage action potentials, and the precramp phase by runs of activity in motor units. Why cramps should be painful is not known; probably the demands of the overactive muscle exceed metabolic supply, causing a relative ischemia and accumulation of metabolites. Overwork of muscle with or without impairment of circulation is also painful. Between cramps, the muscles are normal clinically and electromyographically.

Cramps are known to increase in frequency under certain conditions and with certain diseases. They are frequent during pregnancy for reasons not fully understood. Dehydration and sweating predispose to cramping and are a constant threat to athletes, who try to prevent them by ingesting electrolyte solutions. Exertional cramps are frequent in motor system disease and hypothyroidism and less so in chronic polyneuropathies. Patients undergoing hemodialysis are subject to cramps, which can be suppressed by intravenous hypertonic saline or hypertonic glucose. Rapid rehydration after dehydration is another provocative factor. Focal cramping occurs after partial nerve or root injury and with diseases involving anterior horn cells. In one such condition, the calf muscle on one side is subject to severe recurrent cramps after decompression of the S1 root in lumbar disc disease; in extreme cases, the muscle hypertrophies.

The mechanism of muscle cramping is obscure. In a number of cases with exercise-induced stiffness and muscle pain, sometimes progressing to cramp, below-normal levels of myoadenylate deaminase have been found. The significance of this observation is uncertain. This enzyme, which is present in high concentration in muscle, is thought to function primarily during aerobic exercise and facilitate the regeneration of adenosine triphosphate from adenosine diphosphate through the action of adenylyl kinase. Others assert that low levels of this enzyme are not specific, occurring in such unrelated disorders as hypokalemic periodic paralysis and spinal muscular atrophy (see Layzer for details).

Quinine sulfate—300 mg at bedtime and repeated in 4 h if necessary, or 300 mg tid for diurnal cramping—is an effective medication; diphenhydramine hydrochloride (Benadryl) 50 mg or procainamide 0.5 to 1.0 g can be substituted if quinine is not tolerated. Phenytoin, carbamazepine, propoxyphene, and sometimes clonazepam are even more useful in alleviating repeated daytime cramping.

Tetany, Pseudotetany, and Related Cramp Syndromes

As pointed out on page 1096, a reduction in ionizable calcium and magnesium is associated with involuntary cramplike spasms; in their mildest form they appear as distal carpopedal spasms, but they may involve any of the muscles except the extracocular ones. Stimulation of a muscle through its nerve at certain frequencies (15 to
20 times per second) characteristically reproduces the spasms, and hyperventilation and ischemia increase the tendency. Indeed, the Trousseau sign—carpal spasms with occlusion of the blood supply to the arm—takes advantage of the latter phenomenon. That hypocalcemic tetany is attributable to an unstable depolarization of the axonal membrane of the nerve fiber is shown by (1) the sensitivity of nerve to percussion (tapping over the facial nerve near its foramen of exit induces a facial twitch, or Chvostek sign), (2) the appearance of fast-frequency doublets and triplets of motor unit potentials in the EMG, (3) evocation of spasm by application of a tourniquet to proximal parts of a limb (causing ischemia of segments of nerve beneath the tourniquet), and (4) the regular association of tingling, prickling paresthesias from excitation of sensory nerve fibers. Hypocalcemia also causes a lesser change in the muscle fibers themselves; hence nerve block does not completely eradicate tetany.

A condition resembling tetany but without measurable hypocalcemia is the aforementioned benign cramp syndrome (psuedotetany). In the most severe forms, all skeletal muscles are intermittently locked in spasm, and almost any strong postural or voluntary movement leads to cramp. When this phenomenon is repeated again and again, the overly active muscles begin to hypertrophy. In about half of the authors’ cases, stimulation of nerve at 15 or more per second produced cramp discharges, as in tetany. Biopsies have disclosed no abnormalities of the muscle fibers except for a few ringbinden (circumferential bands of myofibrils encircling a normal core of longitudinally oriented myofibrils). Calcium and diazepam are of no therapeutic value, but some patients respond to phenytoin, quinine, procainamide, or chlorpromazine.

A familial (autosomal dominant) form of the benign cramp syndrome has been reported by Jusic and coworkers; the cramps affected the distal limb muscles, began in childhood and adolescence, and persisted throughout life. Another such family with cramps beginning somewhat later in life and affecting the anterior neck, arm, and abdominal muscles as well as those of the thigh and calf has been described by Ricker and Moxley. Also, as mentioned in Chap. 50, a familial myalgic-cramp syndrome has been associated with deletion of part of the dystrophin gene (but with little or no dystrophic weakness). A tendency to cramp and pain has also been noted in a number of the congenital myopathies and in some families with Duchenne and Becker dystrophies.

Satoyoshi Syndrome Satoyoshi has described a group of patients who, in addition to widespread severe cramping of muscle, showed universal alopecia, amenorrhea, intestinal malabsorption, and sometimes epiphysyeal destruction and retarded growth. Most Japanese patients described by Satoyoshi were under 20 years old, but the cases we have observed have been older. The serum calcium in these patients is normal, and the EMG shows only high-frequency discharges that are characteristic of cramps. A male patient of ours with this condition had decades of chronic diarrhea, alopecia, and continuous and extremely painful calf cramps that looked, from the surface, like fasciculations. This triad virtually identifies the disease. The cause of the disorder is entirely obscure but tentatively presumed to be autoimmune. Glucocorticoids, particularly in high doses over short periods, have been tried with some success; dantrolene has also been used, and we had the impression that plasma exchange may have been helpful in one case.

States of Persistent Fasciculation, Myokymia, Continuous Muscle Fiber Activity, Neuromyotonia, “Stiff-Man” Syndrome, and Schwartz-Jampel Syndrome

This is a confusing group of clinical states, all characterized by some degree of regional continuous muscular activity, that in some cases cannot be fully differentiated from one another. From a clinical perspective we have found it useful to categorize them in groups that are caused by (1) hyperexcitability of the peripheral motor nerves, (2) centrally mediated hyperexcitability of motor output, (3) nonmyotonic hyperexcitability of muscle, and (4) disorders of extracellular matrix proteins that alter muscle membrane excitability.

Hyperexcitability of Peripheral Nerve

This term comprises a set of disorders in which peripheral motor nerve activity is augmented, such that there are excessive, sometimes sustained contractions of the motor unit. Its mildest manifestation is benign fasciculation. In more severe forms, the result is a group of disorders that includes cramp-fasciculation syndrome, neuromyotonia, Isaacs disease, and a variant of the latter in which there is also involvement of the central nervous system (Morvan disease), a disease of potassium-gated ion channels (page 1273). They are not generally familial but several lines of investigation argue that many of these disorders are of an acquired autoimmune nature (Newson-Davis). For example, all but benign fasciculations are associated more often than might be expected with other autoimmune diseases such as myasthenia gravis and many respond to anti-immune therapies such as plasmapheresis. And, in some of these disorders, the patient’s sera possess antibodies to either voltage-gated potassium channels as mentioned or, less frequently, nicotinic acetylcholine (ACh) receptors (Vernino and Lennon).

Persistent Benign Fasciculations A few random fasciculations in the muscles of the calf, small muscles of the hand or of the face, or elsewhere are seen in most normal individuals. They are of no significance but can be a source of worry to physicians and nurses who have heard or read that fasciculations are an early sign of amyotrophic lateral sclerosis. A simple clinical rule is that fasciculations in relaxed muscle are not indicative of motor system disease unless there is associated weakness, atrophy, or reflex change.

Frequently a healthy individual experiences intermittent twitching of a muscle (or even part of a muscle), such as one of the muscles of the thenar eminence, eyelids, calves, or orbicularis oculi. It may continue for days. Lay persons refer to it as “live flesh.” Also, penicillin may destabilize the polarization of distal motor endings and cause twitching. Electromyographically, these benign fasciculations tend to be more constant in location and more frequent and rhythmic than the ominous fasciculations of amyotrophic lateral sclerosis, but such distinctions are not entirely reliable. Quantitative study of the motor unit size may be helpful in these circumstances by demonstrating normally modeled units in the benign form and abnormally large units due to reinnervation in the case of motor neuron disease (see page 1105).

Occasionally, benign fasciculations are widespread and may

Satoyoshi Syndrome Satoyoshi has described a group of patients who, in addition to widespread severe cramping of muscle, showed universal alopecia, amenorrhea, intestinal malabsorption, and sometimes epiphyseal destruction and retarded growth. Most Japanese patients described by Satoyoshi were under 20 years old, but the cases we have observed have been older. The serum calcium in these patients is normal, and the EMG shows only high-frequency discharges that are characteristic of cramps. A male patient of ours with this condition had decades of chronic diarrhea, alopecia, and continuous and extremely painful calf cramps that looked, from the surface, like fasciculations. This triad virtually identifies the disease. The cause of the disorder is entirely obscure but tentatively presumed to be autoimmune. Glucocorticoids, particularly in high doses over short periods, have been tried with some success; dantrolene has also been used, and we had the impression that plasma exchange may have been helpful in one case.

It may continue for days. Lay persons refer to it as “live flesh.” Also, penicillin may destabilize the polarization of distal motor endings and cause twitching. Electromyographically, these benign fasciculations tend to be more constant in location and more frequent and rhythmic than the ominous fasciculations of amyotrophic lateral sclerosis, but such distinctions are not entirely reliable. Quantitative study of the motor unit size may be helpful in these circumstances by demonstrating normally modeled units in the benign form and abnormally large units due to reinnervation in the case of motor neuron disease (see page 1105).

Occasionally, benign fasciculations are widespread and may
last for months or even years. In several of our patients they have recurring in bouts separated by months and lasting several weeks. No reflex changes, sensory loss, nerve conduction, EMG abnormality (other than fasciculations), or increase in serum muscle enzymes are found. Low energy and fatigability in some of these patients may suggest an endogenous depressive illness, yet the fasciculations are not explained by this mechanism. Commonly, patients report a sense that the muscles affected by the twitching are weak but this cannot be confirmed by testing, and several of our patients, curiously the majority of whom were physicians, have complained of equally troubling migratory zones of paresthesias (Romero et al). Pain, of aching or burning type, may increase after activity and cease during rest. Fatigue and a sense of weakness are frequent complaints. We suspect that this fasciculatory state reflects a disease of the terminal motor nerves, for a few of our patients have shown slowing of distal latencies, and Coörs and associates have found degeneration and regeneration of motor nerve terminals. However, the majority of these cases are of a benign nature and settle down in a matter of weeks or months. In the cases reported by Hudson and colleagues, the condition, even after years, did not progress to spinal muscular atrophy, a polyneuropathy, or amyotrophic lateral sclerosis. Eventual recovery can be expected. This conforms to our experience and to that reported from the Mayo Clinic where 121 patients with benign fasciculations, followed in some cases for more than 30 years, showed no progression of symptoms and did not acquire motor neuron disease or neuropathy (Blexrud et al). It should be acknowledged, however, that there are infrequent patients with seemingly benign fasciculations in whom the EMG shows some abnormal features (e.g., rare fibrillations) in numerous muscles and who later develop the other features of motor neuron disease. Carbamazepine, and to a lesser extent phenytoin, has been helpful in reducing the fasciculations and sensations of weakness.

**Cramp-Fasciculation Syndrome** This is a variant of the aforementioned entity in which fasciculations are conjoined with cramps, stiffness, and systemic features such as exercise intolerance, fatigability, and muscle aches. Although affected individuals may be to some degree disabled by these symptoms, the prognosis is good. The salient finding on physiologic studies is that stimulation of peripheral nerves results in sustained muscle firing due to prolonged trains of action potentials in the distal motor nerve. This may be brought out in special electrophysiologic testing as described by Tahmoush and colleagues. In effect, this is a mild form of neuromyotonia (see later). In a small number of patients with cramp-fasciculation syndrome it is possible to demonstrate the presence of autoantibodies directed against voltage-gated axonal potassium channels. Carbamazepine or gabapentin may be beneficial.

There are, in addition to the aforementioned benign states, several syndromes of abnormal muscle activity. The main ones are myokymia, a state of successive contractions of motor units imparting an almost continuous undulation or rippling of the overlying body surface, and several syndromes of continuous muscle fiber activity.

**Myokymia** This state of abnormal rippling muscle activity, as defined earlier, may be generalized or limited to one part of the body, such as the muscles of the shoulders or of the lower extremities. It is observed most often with regeneration of peripheral nerve following injury, as in the facial palsy of Guillain-Barré syndrome, and thus it is most often neuropathic in nature. In the EMG, myokymic discharges consist of groups of 2 to 10 potentials, firing at 5 to 60 Hz and recurring regularly at 0.2- to 10-s intervals. They arise in the most peripheral parts of the axon of chronically damaged nerves. In some patients, cramping is associated and, indeed, muscles about to cramp may twitch or show spontaneous rippling contractions; the cramping may be associated with sweating. Thus, myokymia, fasciculation, and cramping are closely related but not clinically identical conditions.

**Continuous Muscle Fiber Activity (Isaacs Syndrome)** The relation of myokymia to the state called continuous muscle fiber activity is ambiguous. Sporadically, in the neurologic literature, there have been described patients whose muscles at some point begin to “work” continuously (see Isaacs). Terms such as neuromyotonia and widespread myokymia with delayed muscle relaxation are additional names that have been applied to what is essentially the same condition. At the moment, there is little reason to distinguish one from another except in gradations of severity. In each case the excessive and spontaneous activity can be attributed to hyperexcitability of terminal parts of motor nerve fiber, possibly as a result of a partial loss of motor innervation and compensatory collateral sprouting of surviving axons (Coörs et al, Valli et al). Twitching, spasms, and rippling of muscles (myokymia) are evident, the latter being the main clinical sign. In advanced cases there is generalized muscle stiffness and a sense of weakness. Complaints of muscle aching are usual, but severe myalgia is uncommon. The tendon reflexes may be reduced or abolished. Any muscle group may be affected. The stiffness and slowness of movement make walking laborious (“armadillo” syndrome); in extreme cases, all voluntary movement is blocked. The muscle activity persists throughout sleep. The continuous visible and painful cramps of Satoyoshi disease are difficult to distinguish from myokymia.

General and spinal anesthesia do not always suppress the muscular activity, but curare does; nerve block usually has no effect or may reduce the activity, as in the case described by Lütschg and colleagues. The EMG findings are much the same as those described earlier.

This syndrome arises in childhood or adult life, sometimes in association either with a polyneuropathy or with an inherited type of episodic ataxia that is variably responsive to acetazolamide or remits spontaneously. An inherited form of continuous muscle fiber activity has been traced to a gene mutation on chromosome 12 and is attributed to a peripheral nerve K channel abnormality (Gutmann and Gutmann). In addition to the association with polyneuropathy, a state of continuous muscular activity has also been described with lung cancer and thymoma, with or without myasthenia, in which cases an immune mechanism has been inferred (see reviews by Thompson and by Newsom-Davis and Mills). An association of continuous muscle fiber activity with psychosis or a severe sleep disorder was described by Morvan under the name chorée fibrillaire as discussed in the previous chapter (see also page 1273, Serratrice and Azalay). Most cases appear to be idiopathic, however.

**Treatment** Phenytoin or carbamazepine often abolishes the continuous muscular activity and causes a return of reflexes. Acetazolamide has been helpful in some other cases (Celebiosy et al). Many of the idiopathic cases, as already noted, will improve spontaneously after several years, but plasma exchange may be tried if the symptoms are intractable.
Centrally Mediated Motor Hyperexcitability

Stiff-Man Syndrome  This is a condition of persistent spasms, particularly of the proximal lower limbs and lumbar paraspinal muscles, forcing the patient eventually to lie helplessly in bed with the feet in equinus position and the legs extended. It was originally described by Moersch and Woltman in 1956 as stiff-man syndrome. Since then, many examples have been reported all over the world and the term stiff-person syndrome has been used to indicate its occurrence also in women.

The onset is insidious, usually in middle life, and men and women are affected equally. No genetic predisposition is known. At first the stiffness and spasms are intermittent; then, gradually, they become more or less continuously active in the proximal limb and axial trunk muscles and increasingly painful. The spasms impart a robotic appearance to walking and an exaggerated lumbar lordosis. Attempts to move an affected part passively yield an almost rock-like immobility, perceptibly different from spasticity, parataonia, or extrapyramidal rigidity. Muscles of respiration and swallowing and those of the face may be involved in the more advanced cases, but trismus, a common feature of tetanus, does not occur. We have observed brief periods of cyanosis and respiratory arrest during episodes of intense spasm, and one of our patients died during such an episode. Eye muscles are rarely affected. Any noise or other sensory stimulus or attempted passive or voluntary movement may precipitate severely painful spasms of all the involved musculature. The tendon reflexes are normal if they can be tested. The affected muscles, particularly the lumbar paraspinals and glutaei are extremely taut when palpated. It is this axial spasm that is most characteristic of the disease and gives rise to a characteristic lumbar lordosis over time.

A similar stiffness of one limb (“stiff-limb” syndrome) has been differentiated from the generalized variety by Barker and colleagues and others (see Saiz et al; Brown et al), but it seems to us to be part of the same illness, especially since most of the localized cases have antibodies to glutamic acid decarboxylase, as described below. There is, however, no axial spasm or exaggerated lordosis; the condition begins in one leg and spreads to its opposite but remains isolated to the lower extremities. This limited form of spasm is similar to localized tetanus.

In keeping with the presumed autoimmune mechanism, plasma exchange, high-dose corticosteroids, or intravenous gamma globulin are helpful in some patients, albeit for only several weeks or months. Several of our patients have required infusions of gamma globulin for several years at intervals of 6 to 12 weeks but nevertheless became disabled if the dose of diazepam was reduced below 200 mg/day. A small randomized trial of intravenous immune globulin conducted by Dalakas and colleagues had demonstrated the efficacy of this treatment; in their study, the benefits varied in duration from 6 weeks to 1 year.

Clinically, the stiff-man syndrome must be distinguished from tetanus (page 1030 and further on), the Isaacs syndrome (see earlier), and the rare syndrome of subacute myoclonic spinal neuronitis, described on page 1066. In both the stiff-man syndrome and myoclonic spinal neuronitis, the intense spasms and stiffness of muscles are due to disinhibition of interneurons (possibly via GABA-ergic Renshaw cells) in the gray matter of the spinal cord. These syndromes of continuous muscle activity, except perhaps the stiff-man syndrome, are, as a rule, usually distinguishable clinically and electromyographically from extrapyramidal and corticospinal abnormalities such as dystonia, dyskinesia, and rigidity; there is only a superficial resemblance to spastic paraparesis.

Congenital Neonatal Rigidity  A “stiff-infant” syndrome, observed by Dudley and colleagues in four families of mixed heritage, should probably be included in this general category. The condition came to medical attention because of respiratory distress due to a generalized muscular rigidity beginning at about 2 months of age. The rigidity spread slowly from cervical muscles to those of the trunk and limbs, and, as it persisted, slight hypertrophy developed. The use of respiratory aid and a feeding gastrostomy enabled the infants to survive. The rigidity slowly diminished in the second year of life. The clinical course was unlike that of tetanus. In fatal cases there were zones of fiber loss, with fibrosis in skeletal and cardiac muscles, and a greater than normal variation in fiber size. Altered Z lines were observed electron microscopically in some fibers.

Primary Hyperexcitability of Muscle

At least two varieties of primary muscle disorder are known, not myotonic in nature, that produce continuous muscle activity. The first described below is due to a defect in the muscle membrane; the second has been found to be a disease of the extracellular matrix of muscle.

Rippling Muscle Disease  Ricker and Burns and their associates have described a rare familial disorder (autosomal dominant) in which muscles display an unusual sensitivity to stretch, manifest
by rippling waves of muscle contraction. Percussion of muscles yields a pronounced and painful local mounding. Similar familial and sporadic cases have been traced to a defect in caveolin, a protein otherwise implicated in one of the muscular dystrophies (Vogger). An autoimmune process has been implicated in some other cases (Muley and Day). The EMG discloses neither myotonic discharges nor the action potentials of cramp, indicating that the basic abnormality is in the muscle membrane.

**Schwartz-Jampel Syndrome** A syndrome characterized by continuous muscle fiber activity with stiffness and blepharospasm, accompanied by obvious dysmorphic features (dwarfism, pinched face with low-set ears, blepharophimosis, high-arched palate, receding chin, diffuse metaphyseal and epiphyseal bone dysplasia with flattened vertebrae), was crystallized by Schwartz and Jampel in 1962. It has also been reported under other names including *myotonic chondrodystrophy*. Intelligence is usually preserved. There may be percussion myotonia. The stiff muscles disturb gait.

The muscle stiffness is the result of frequent, almost continuous muscle activity with a combination of normal motor units as well as high-frequency discharges and afterdischarges similar to those seen in Isaacs syndrome. The discharges can be demonstrated to arise from muscle fibers themselves since the activity is not obliterated by curare. Agents such as procainamide, which block sodium channels in muscle, inhibit the discharges, just as they do in some other myotonic disorders. However, Spans and associates, who have reviewed the clinical, EMG, and histologic features of 30 cases of this syndrome, report a diminished chloride conductance by the sarcolemma, which can be suppressed by procainamide or even better by mexiletine.

The disorder is usually inherited as an autosomal recessive trait that is caused by mutations in perlecain, a heparin-sulfate proteoglycan that is bound to the basement membranes of skeletal muscle and cartilage. Loss of function of the protein perturbs the organization of the basement membrane leading to an altered clustering of ACh esterase and abnormal expression of ion channels. Electron microscopic studies of muscle have yielded inconsistent findings: dilated T system, Z-band streaming, and dilatation of mitochondria; in addition, in the patient reported by Fariello and colleagues, muscle biopsy disclosed signs of denervation (group atrophy). In the latter case, treatment with procainamide, phenytoin, diazepam, and barbiturates was ineffective.

The condition described by Aberfeld and coworkers, of two siblings in whom myotonia was combined with dwarfism, diffuse bone disease, and unusual ocular and facial abnormalities and thought by them to represent a unique disorder, is probably a variant of the Schwartz-Jampel syndrome.

**Muscle Contracture, Pseudomyotonia, Tetanus, and Related States**

**Physiologic Contracture Due to Phosphorylase Deficiency (McArdle) and Phosphofructokinase Deficiency (Tarui)** These are examples of an entirely different type of painful shortening and hardness of muscle. In both these diseases, an otherwise healthy child, adolescent, or adult begins to complain of weakness and stiffness and sometimes pain on using the limbs. Muscle contraction and relaxation are normal when the patient is in repose, but strenuous activity, especially under conditions of ischemia, causes the muscles to shorten gradually, due to a failure of relaxation. The contracted muscles in these disorders—unlike muscles in cramp, continuous muscular activity syndromes, or myotonia and other involuntary spasms—no longer use energy. During contraction, the muscles are almost silent electrically in the EMG. This condition is spoken of as *pharmacologic or physiologic contracture*. McArdle and Tarui diseases are discussed more fully beginning on page 1232.

**Pseudomyotonia** This phenomenon is observed in *hypothyroidism*, where the muscle fibers contract and relax slowly. This response is readily demonstrated in eliciting tendon reflexes, particularly the Achilles reflex. The muscles are large and subject to myoedema; when used, they may show waves of slow contraction. The basis of this disorder appears to be a slowness in the reaccumulation of calcium ions in the endoplasmic reticulum and in the disengagement of thin actin and thick myosin filaments. The EMG may show afterpotentials following voluntary contraction, but they do not resemble the typical waning discharges ("myotonic runs") of true myotonia.

A closely related syndrome, wherein painless contracture is induced by exercise, has been described by Lambert and Goldstein, and by Brody. Whereas muscle contraction is normal, the relaxation phase becomes increasingly slow during exercise. Lambert and coworkers referred to it as an unusual type of myotonia, and Brody, as a decrease of relaxing factor. The slow relaxation of muscles has also been attributed to a decreased uptake of calcium by the sarcoplasmic reticulum. In some cases, the disease is transmitted as a recessive trait; the gene defects are mutations that impair the function of a sarcoplasmic reticular calcium adenosine triphosphatase (ATPase; Odermatt et al). In other instances, the disease is transmitted as a dominant trait that is not genetically linked to the calcium ATPase.

**Tetanus** (See page 1030) This disorder is characterized by persistent spasms of skeletal muscles, owing to the effect of the tetanus toxin on spinal neurons (Renshaw and other cells), the natural function of which is to inhibit the motor neurons. As the condition develops, activities that normally excite the neurons (i.e., voluntary contraction and startle from visual and auditory stimulation) all evoke involuntary spasms. Sleep tends to quiet them, and they are suppressed by spinal anesthesia and curare. The EMG shows the expected interference pattern of action potentials. Once the muscle is involved in persistent contraction, it is said that the shortened state is not abolished by procaine block or severance of nerve (in animals), but this so-called *myostatic contracture* has not been demonstrated in humans.

The effect on the inhibitory neurons is analogous to that of strychnine. There is also an action of the tetanus toxin at the neuromuscular junction, which has been more difficult to evaluate in the face of its powerful central action. Having injected this toxin locally in animals, Price and associates have demonstrated its localization at motor end plates. It binds with ganglioside in the axon membrane and is transported by retrograde flow to the spinal cord, where it induces local tetanus effects. Neurons that innervate slow-twitch type 1 muscle fibers are more sensitive than those supplying fast-twitch type 2 fibers. Presynaptic vesicles increase, ACh is blocked, and terminal axon injury may paralyze muscle fibers. Fibrillation potentials and axonal sprouting follow. The similarities to stiff-man syndrome have already been mentioned.

**Black Widow Spider Bite** The toxin produced by this spider, within a few minutes of the bite, leads to a striking syndrome of
cramps and spasms and then a painful rigidity of abdominal, trunk, and leg muscles. The spasms are followed by weakness. There is also vasoconstriction, hypertension, and autonomic hyperactivity. If death does not occur in the first 24 to 48 h, recovery is complete.

The spider venom has a presynaptic localization and rapidly releases quanta of ACh. The vesicles are depleted. There is some evidence that the venom prevents endocytosis of the vesicles by inserting itself into the presynaptic membranes, causing a disturbance of ionic conductance channels (Swift).

Treatment, which is more or less empiric, consists of calcium gluconate infusions. Intravenous magnesium sulfate also helps to reduce the release of ACh and control the convulsions that sometimes occur. There is a reconstituted antiserum that is available in regions where such envenomation is frequent.

Malignant Hyperthermia (See page 1272) This condition is also characterized by an acute onset of generalized muscular rigidity accompanied by a rapid rise in body temperature, metabolic acidosis, and myoglobinuria. It is invariably induced by anesthetic agents and other drugs.

Myalgic States

Many of the muscle diseases described in the preceding pages are associated with aching and discomfort. These are particularly prominent in conditions that are accompanied by cramp and biochemical contracture (phosphorylase and phosphofructokinase deficiency). Ischemia of muscle—that is, intermittent claudication—is also painful, as is dystonia in some cases. Muscle weakness that imposes persistent abnormal postures on the limbs may cause stretch injury of muscles and tendons. This is observed in a number of the congenital myopathies and dystrophies. In all these conditions, clinical study will usually disclose the source or sources of the pain.

Diffuse muscle pain, which merges with malaise, is a frequent expression of a large variety of systemic infections—e.g., influenza, brucellosis, dengue, Colorado tick fever, glanders, measles, malaria, relapsing fever, rheumatic fever (“growing pains”), salmonellosis, toxoplasmosis, trichinosis, tularemia, and Weil disease. When the pain is intense, especially if it is localized to one side of the lower chest and abdomen, the most likely diagnostic possibility is epidemic myalgia (also designated as pleurodynia, “devil’s grip,” and Bornholm disease, due to Coxsackie virus infection). Poliomyelitis may be accompanied by intense pain at the onset of neurologic involvement, and later the paralyzed muscles may ache. This is true also of the Guillain-Barré syndrome, in which the pain may precede weakness by several days. Little is known about the pathologic basis of the muscular pain in these diseases; it is not due to muscle inflammation. Mild muscle pain is a frequent but not a necessary accompaniment of polymyositis and dermatomyositis.

Polymyalgia Rheumatica The major consideration in elderly and middle-aged patients with pain in proximal muscles of the limbs is polymyalgia rheumatica. This subject is mentioned briefly in other sections of this book in relation to back and extremity pain (page 189) and to temporal arteritis, to which it is closely connected (page 159). The muscular soreness may be diffuse or asymmetrical, particularly in the proximal arms and shoulders. Every movement is reported as stiff and painful. The periarticular tissues and their muscular attachments are affected primarily and may be tender, but this is difficult to interpret, since it may be found in otherwise healthy individuals. The sedimentation rate is greatly elevated in the majority of patients, and a 48-h trial of prednisone, by alleviating muscle pain, confirms the diagnosis. In the context of muscle pain, systemic symptoms such as weight loss, headache, and fatigue, as well as mild anemia, are particularly suggestive of polymyalgia rheumatica.

Fibromyalgia This would appear, by definition, to represent an inflammation of the fibrous tissues of the muscles, fascia, aponeuroses, and possibly nerves as well. Unfortunately, the pathologic basis of this state remains obscure. Only some clinical facts are at hand. During the first movements after a period of inactivity, a muscle or group of muscles may become painful and tender, particularly after exposure to cold, dampness, or minor trauma, but often for no reason that can be discerned. One looks in vain for signs of tendinous or arthritic disease. The neck and shoulders are the most common sites. Sometimes firm, tender areas, up to several centimeters in diameter, can be palpated within the muscles (“fibrotic nodules”), and active contraction or passive stretching of the involved muscles increases the pain—points said to be of diagnostic value, but still disputed. Often, symptoms such as mental and physical fatigue, insomnia, and headache are associated and raise the suspicion of an anxiety state or depression. In a few instances the condition clears up in a few weeks; local heat and massage and local injections of anesthetics or steroids are found to give comfort while symptoms are present, but most often it becomes a chronic condition.

The chronic form of fibromyalgia presents far greater problems, usually disabling the patient and causing a change in accustomed habits and employment. It has become one of the prime diagnoses made by rheumatologists and physiatrists, but the patient may first come to the attention of a neurologist. Muscle pain is the primary symptom, with fatigue and the other aforementioned complaints added as an afterthought by the patient, or the muscular symptoms are elicited in exploring a case of the equally vexing condition now called “chronic fatigue syndrome” (pages 190 and 435). There is a great preponderance of women among these patients, and in the majority the illness is not predated by any particular factor, although a few have a viral prodrome or recently preceding trauma.

Most definitions of the syndrome have been circular or somewhat arbitrary. Those now in general use are similar to the one proposed by a committee of the American College of Rheumatology. The basis for diagnosis is the presence of widespread pain including focal areas of pain (trigger points) that can be produced by 4 kg of digital pressure in 11 of 18 typical locations over muscles, tendons, or bone—these are concentrated around the shoulders and paraspinal regions—and there is no requirement for the presence of the several common systemic complaints that accompany the illness in most patients (fatigue, difficulty concentrating, sleeping difficulty, or anxiety). There is said to be a knot or fibrous band at the site of tenderness, but this is difficult to verify.

There is, to say the least, controversy regarding the nature of these pressure points and the validity of methods used to elicit them, since mechanical dolorimetry often suggests that these patients have a reduced tolerance to pain at all sites. But there is also uncertainty regarding the relationship of the symptoms to underlying depression. In the past, similar pains were associated with cases of irritable bowel or irritable bladder syndromes, dysmenorrhea, chronic headache, and cold intolerance. Depending upon
how broad a definition one allows for the widespread pain and painful trigger points, most or all patients in our experience manifest many of the same complaints as those with the chronic fatigue syndrome, which is discussed in Chap. 24. Authorities on the subject, however, have claimed that in the majority of patients, formal assessment by modern criteria fails to confirm the presence of depression and that, when depression does coexist with the muscular complaints, the two are discordant temporally and in severity. While we acknowledge that antidepressants often give disappointing results and that in our practice there have been several young women with fibromyalgia who appeared to be psychologically stable and lacked depression, these are the exceptions. The literature eschews the use of corticosteroids for treatment of the pain, but we have had occasion to see two patients whose symptoms were relieved when these medications were used for other purposes.

It can be said in conclusion that fibromyalgia remains a problematic illness, defined by a pattern of pain that justifies its name. Despite attempts to objectify the physical symptoms, psychiatric factors should not be overlooked. This condition is a “favorite” illness with physiotherapists, who claim that their physical measures are helpful, as they may well be. Rarely, a similar syndrome is the forerunner of what proves, after some days, with the onset of neurologic signs, to be a radiculitis, brachial neuritis, or outbreak of herpes zoster (see Goldenberg).

**Other Myalgic States**

An impressive polymyalgia is the common one that follows excessive exercise. Often the patient observes that aching pain occurs not at the time of activity but some hours or even a day or two later, resembling the discomfort following the excessive use of unconditioned muscles. The muscles are sore and there is an intolerance of exercise and physical exertion. This is a natural phenomenon and is self-limiting. When such a state persists indefinitely and a program of conditioning exercises does not alleviate the pain, it represents a special category of disease. In a few instances an increased sedimentation rate or other laboratory aids may clarify the diagnosis, and muscle biopsy may reveal a nonspecific interstitial nodular myositis or the giant-cell arthritis associated with polymyalgia rheumatica. A few individuals go on to have the features of the previously described fibromyalgic syndrome. However, this cluster of symptoms most often occurs without explanation, and one can only suspect an obscure infection or a subtle aberration of muscle metabolism, presently impossible to demonstrate. Reference was made earlier to the finding of a myoadenylate deaminase deficiency in some of these cases. Sometimes a rapid and excessive rise of creatine kinase (CK) after strenuous exercise will provide a clue (a slight to moderate elevation of CK is to be expected after heavy or prolonged exercise). There is also a group of patients who have idiopathic leg pain during rest after activity. Some families afflicted in this way are forced to live a sedentary existence. The condition does not respond to analgesics. In two cases, a deficiency of calcium-ATPase was found and reportedly alleviated by a calcium channel blocker such as verapamil, 120 mg qid (Walton; Taylor et al). It must be distinguished from Fabry disease (page 1159), from the syndromes of painful legs and moving toes, and from the restless leg syndrome (page 339).

The problem of a muscular pain-fasciculation syndrome was discussed earlier. In thin, asthenic adults who exhibit rather vague polymyalgia without other abnormalities, with or without cramps and fasciculations, the authors have found it difficult to exclude hysteria or other neurosis and depression. Before concluding that the condition has a psychiatric basis, it is important in every such individual to search for evidence of a rheumatic disease or the myopathy that may accompany hypothyroidism, hyperparathyroidism and renal tubular acidosis, hypophosphatemia, hypoglycemia, and the intrinsic phosphorylase or phosphofructokinase defect. Patients with these latter diseases often complain of soreness, stiffness, and lameness after strenuous muscular effort. According to Mills and Edwards, the most valuable screening tests are the sedimentation rate and serum CK concentration. Other patients probably have an obscure metabolic myopathy, presently undiagnosable. In every reported series, such as that of Serratrice and coworkers, about half of the cases with diffuse myalgia are undiagnosable. This coincides with our own experience.

**LOCALIZED MUSCLE MASSES**

Masses may be found in one or many muscles in a variety of clinical settings, and the clinical findings in each one have a different significance.

**Muscle rupture** is usually caused by a violent strain attended by an audible snap and then a bulge, which appears when the muscle contracts. A weakening in contractile power and mild discomfort are usually noted by the patient. The biceps brachii and soleus muscles are most often affected. Treatment is by surgical repair; if that is delayed, little can be done for the condition.

**Hemorrhage into muscle** may occur as a consequence of trauma, as a complication of the use of anticoagulants, in hematologic diseases, in severe myotonia, or after a minor trauma in a patient with Zenker degeneration of muscle who is convalescing from typhoid fever or some other infection. Runners may acquire painful localized hematomas in leg muscles.

Tumors include **desmoid tumor** (a benign massive growth of fibrous tissue observed most often in parturient women and after surgery), **rhabdomyosarcoma** (a highly malignant tumor with strong liability to local recurrence and metastasis), **liposarcoma**, and **angiomia**. Large neurofibromas or neurofibrosarcomas beneath large muscles such as the hamstring may be difficult to differentiate by physical examination or magnetic resonance imaging (MRI) from masses within the muscle. **Pseudotumorous** growths, sometimes massive, may follow injury of a muscle. Interlacing regenerating muscle fibers and fibroblasts compose the mass. Excision of the entire muscle had been undertaken in several cases in the belief that the growth was a rhabdomyosarcoma, whereas it is actually a benign reaction to trauma (Kakulas and Adams).

**Thrombosis of arteries** or, more often, of veins causes congestion and infarction of muscle. A special type of **muscle infarction** occurs in patients with complicated and poorly controlled diabetes mellitus (Banker and Chester). Usually the infarction involves the anterior thigh, and occasionally other muscles of the lower limb. The major symptoms are the sudden onset of pain and swelling of the thigh, with or without the formation of a tender, palpable mass. Recurrent infarction of the same or opposite thigh is characteristic. The stereotypical clinical picture and the striking MRI appearance obviate the need for diagnostic muscle biopsy. The extensive infarction of muscle is due to the occlusion of many medium-sized muscular arteries and arterioles, most likely the result of embolization of atheromatous material from eroded plaques in the aorta or iliac arteries. Recognition of this complication and immobilization of the limb are of prime practical importance, since muscle biopsy and early ambulation may cause serious hemorrhage into the infarcted tissue.

The **pretibial syndrome**, also well recognized, follows direct
trauma or excessive activity (marching, exercising of unconditioned muscles). There is swelling of the extensor hallucis longus, extensor digitorum longus, and anterior tibial muscles. Being tightly enclosed by the bones and pretilial fascia, the swelling leads to ischemic necrosis and myoglobinuria. Permanent weakness of this group of muscles can be prevented by incising the pretilial fascia and thereby decompressing the affected muscles.

**Myositis Ossificans** This condition involves the deposition of bone within the substance of a muscle. Two types are recognized. One is a localized form that appears in a single muscle or group of muscles after trauma, and the other is a progressive, widespread ossifying process, entirely unrelated to trauma, in many muscles of the body.

**Localized (Traumatic) Myositis Ossificans** After a muscle tear, a single blow to the muscle, or repeated minor trauma, a painful area develops in the muscle. It is gradually replaced by a mass of cartilaginous consistency, and within 4 to 7 weeks’ time a solid mass of bone can be felt and seen in radiographs. As would be expected, this most frequently happens in vigorous adult men; the inner thigh muscles (in those who ride horses) and to a lesser extent the pectoralis major and biceps brachii are the most common sites of the abnormality. The mass tends to subside after several months if the patient desists from the activity that produced the trauma.

**Generalized Myositis Ossificans (Fibrodysplasia Ossificans Progressiva)** This disease, first described by Munchmeyer in 1869, has since been referred to by his name or as myositis ossificans progressiva. It is rare, although Lutwak, in 1964, was able to collect 264 cases from the literature. The cause is unknown, but the disease is probably inherited as an autosomal dominant trait. It consists of widespread bone formation along the fascial planes of muscles and has its onset in infancy and childhood in 90 percent of cases. Biopsies of early indurated swellings have revealed extensive proliferation of interstitial connective tissue in which little inflammatory cell reaction is found. Within a few weeks, the connective tissue becomes less cellular and retracts, compressing the adjacent muscle fibers. Osteoid and cartilage formation occur at a later stage, developing in the connective tissue and enclosing relatively intact muscle fibers.

Nearly 75 percent of all reported cases have been associated with congenital anomalies, the most frequent of which is a failure of development of the great toes or thumbs and less often other digits. Less frequently, there is hypogenitalism, deafness, and an absence of upper incisors. The first symptom is often a firm swelling and tenderness in a paravertebral or cervical muscle. There is, in addition, a mild discomfort during muscle contraction, and the overlying skin may be reddened and slightly swollen. Trauma may be recalled as the initiating factor, but as the months pass, other muscles not injured in any recognizable way become similarly involved. At first, radiographs reveal no important changes, but within 6 to 12 months, calcium deposits are observed, and one can feel stony-hard masses within the muscles. As the disease advances, limitation of movement and deformities become increasingly evident. Calcified bridges between adjacent muscles and across joints lead to rigidity of the spine, jaw, and limbs; scoliosis; and limited expansion of the thorax. Ultimately, the patient is virtually “changed to stone.”

The principal problem in diagnosis is to differentiate generalized myositis ossificans from calcinosis universalis. The latter usually occurs in relation to scleroderma or polyarthropathy and is characterized by calcium deposits in the skin, subcutaneous tissues, and connective tissue sheaths around the muscles; in myositis ossificans, there is actual bone formation within the muscles. The pathologic data are often too meager to justify this sharp distinction. The prolonged ingestion of large doses of vitamin D may also result in the deposition of masses of calcium salts around muscles, joints, and subcutaneous tissue. Calcific deposits, perhaps true ossification, may occur in the soft tissues around the hips and knees of paraplegics and rarely following a hemiplegia (“paralytic myositis ossificans”).

Myositis ossificans may undergo spontaneous remissions and may stabilize for many years, during which the patient is capable of adequate function. In other cases, progression leads to marked debilitation and respiratory embarrassment, the final illness often being a terminal pneumonia or other infection.

The molecular basis for myositis ossificans is not known, but it has been suggested that one causative defect is the overexpression of bone morphogenic protein. In mice, the forced expression of this protein induces heterotopic bone formation. It is likely that the primary problem arises either because of inappropriate expression of one element of the protein or of excessive binding between signaling proteins and their receptors (Glaser et al).

**Treatment** The administration of a diphosphonate [ethylene-1-hydroxy-1,1-diphosphate (EHDP), 10 to 20 mg/kg orally], a compound that inhibits the deposition of calcium phosphate, has been said to cause regression of new swellings and to prevent calcification (Russell et al). Some of the calcium deposits in calcinosis universalis have receded in response to prednisone, and because of the unclear relationship of this disease to generalized myositis ossificans, it is probably advisable to try this form of therapy as well. Excision of bony deposits may be undertaken if it is certain that they are the cause of particular disabilities.

PART 6

PSYCHIATRIC DISORDERS
To understand mental disorders, one must know something of how the brain functions, comprehend the basics of human psychology and how life’s circumstances affect behavior, and at the same time, the effective physician must always be sensitive to the psychological needs of his patients and express a sincere desire to help them. The first two of these objectives require special study; the latter ones are more innate qualities, found in all good physicians. Indeed, the societal recognition awarded our profession is the result of sympathy for the sick and the willingness to put the patient’s welfare ahead of our own—attributes that meet their greatest challenge in dealing with the mentally ill.

Mental disorders pose a number of special problems not met in other fields of medicine. First, there are such wide variations in personality, character, and behavior that the point where normal ends and abnormal begins is sometimes difficult to determine. Second, most of the methods of studying mental illness are quite subjective, derived mainly from the physician’s perceptions of the inner thoughts and purposes of the patient and from the patient’s powers of narration in revealing his symptoms. The patients’ capacities to provide this information vary with intelligence, personality, education, and cerebral function. Only with some knowledge of the patient’s natural endowment, education, premorbid personality, cultural background, and stability of emotional control, can such differences be understood. Third, and most unusual for the neurologist, it is easily appreciated that the classic mental diseases are not due to obvious lesions in one part of the brain, or even in one ensemble of physiologically or neurochemically related systems of the brain. Finally, the clinical entities of mental disease presented in the following chapters are not easily verifiable by laboratory tests or postmortem examination.

In attempting to study psychiatric disorders, one must be aware of another, more abstruse and essentially theoretical problem. Here, physicians find that there are two different and seemingly antithetical approaches to disordered nervous function—one proceeding along strictly medical or neurologic lines, the other, psychologically based. These two types of data, one drawn from observations of the patient’s behavior, the other from the patient’s introspections are acknowledged and incorporated. It must be emphasized that the terms neurologic and psychologic in this context do not necessarily refer to the activities of neurologists and psychiatrists. They are merely convenient terms for two distinct approaches to mental disorders.

This brings us face to face with a theoretical problem that is posed by more complex psychiatric diseases of the brain. The neurologic approach begins with the premise that all clinical manifestations of a nervous disorder are expressions of a pathologic process (disease) within the nervous system. This process may be obvious (such as a tumor or cerebral infarct), or it may be impossible to detect with the light and electron microscope (such as delirium tremens). Admittedly, brain processes such as perceiving, thinking, remembering, symbolization, are deranged but not readily reducible to a coherent biological system.

The mode of approach to disordered mental function and behavior, which one may term the psychologic, or psychodynamic, has as its main premise that the disordered function has its roots in and is understandable largely in terms of previous or present life experiences. Certain abnormalities of behavior, emotional immaturity, and inability to adjust to the challenges and opportunities of everyday life are thought to stem from an inadequate development of personality, distressing experiences in early life, or both. Some of these experiences are remembered (i.e., “conscious”); others are said to be suppressed or forgotten (i.e., “subconscious or unconscious,” according to psychoanalytic theory) and recalled only with difficulty or by questioning or through the free-association method of psychoanalysis. The principal method is to construct a kind of psychologic autobiography of the individual, with particular emphasis on early life experiences, and to search it for the roots of the present psychologic difficulty. Psychiatrists of this persuasion have formulated a number of psychologic mechanisms whereby symptoms are produced, and they speak of them in a language rather unfamiliar to most physicians—e.g., conflict, repression, conversion, projection, displacement of affect, conditioning, and arrest or fixation of libido. The purpose of this approach is not only to determine causality but also to understand the patient’s current behavior in the light of past experiences and to use this under-
standing to effect change. By frank discussion and guidance, the physician endeavors to
demonstrate the relationship of the patient’s symptoms to abnormal behavior patterns and
reactions, and, by a kind of reeducation, i.e., psychotherapy, to assist in bringing about an
understanding of the problems and improved ways of coping with them. As an intellectual
enterprise, however, the psychologic method alone, although yielding interesting data con-
cerning the patient’s background and the evolution of their particular symptoms in their
form and content, does not provide a complete explanation of disease.

The two methodologies of neurologic and psychiatric medicine are both valid but
have different roles. In diagnosis, one begins always with a classic medical approach,
assuming every symptom to be an expression of disease. This method is relevant also to
a theoretical formulation of disease processes. In reference to therapy and management,
the psychiatric approach is sometimes the only rational (and available) methodology. In
other circumstances, the spheres of the two methodologies tend to overlap. The two meth-
ods operate at different levels and are of principal use in different types of nervous aber-
rations. In the diagnosis and management of difficulties in adjusting to life’s circumstances and in certain disorders of personality and character, which constitute such a large and
important part of medicine and psychiatry, the psychologic approach achieves maximal
credence. The psychiatric approach has been highly successful at focusing on the inter-
action between an individual’s traits and his or her complex environment and is not easily
framed in neurologic terms. This unitary view of mental disease also allows for the poss-
ibility that changes in the environment and even in the patient’s mental state can cause
changes in the functioning of the brain. It is fair to say that this apparent clash of views
between mentalism on the one hand and on the other hand the mind as a property of the
physical brain has been settled in favor of the neurologic view. It is supported to some
degree by the observations that every known psychiatric symptom can be reproduced by
well-defined cerebral diseases, and every major neurologic disease of the cerebrum may
be attended by symptoms of psychiatric disease. Every disorder of function must have a
structural or physiologic basis unless one adheres to a purely psychic view in which human
behavior is not considered to be a product of brain function. This is the position of the
mind-body problem most acceptable to neurologists. This concept of “disorders of mind
arising in brain” is also subscribed to by most modern psychiatrists (Andreasen). Admit-
tedly, neuropsychiatric monism has not had universal acceptance. Western philosophers,
from Plato in ancient times through Descartes, James, and, more recently, Sherrington and
Eccles, broadly speaking have been dualists, holding that body and mind are independent
systems, each susceptible to its own disorders.

This brings us to another of the crucial problems in neurology and psychiatry—that
of defining a disease of the nervous system and distinguishing it from a social or psycho-
logic maladjustment. Failure to do this has resulted in confusion as to the legitimate spheres
of medical activity and has been an obstacle to research. The present authors define a
disease of the nervous system as any condition in which there is a visible, physiologic,
biochemical, or other subcellular lesion or in which there is reasonable evidence of its
existence on the basis of stereotypy of clinical expression and of genetic and collateral
laboratory data. Goodwin and Guze offer a slightly different definition of psychiatric dis-
ease—as any cluster of symptoms and signs that occur with such consistency as to permit
the prediction of their outcome. In contrast, an abnormal psychologic reaction is defined
as a disorder of psychic function and behavior caused by a maladjustment in social relations
or a disordered response to life’s difficulties not based directly on a known disease process
or lesion.

Certain mental abnormalities have an uncertain status vis-à-vis this division and are
subject to double interpretations, depending on one’s premises. For example, persistent
anxiety state without obvious cause in a previously healthy adult would be viewed by
some psychiatrists as a reaction of fear of some unconscious threat. Others would consider
it the manifestation of a genetic disease in which some biochemical disturbance, as mys-
terious as was hyperthyroidism a century ago, developed de novo. Further challenging our
current conceptions is how to interpret the co-opting of basic mechanisms of the limbic
system by thought processes to produce affective states such as depression. Is a susceptibility to trigger such mechanisms a disease, a genetic proclivity, or does it reflect a normal spectrum of activity? Since the nature of the condition is unsettled, it is treated by physicians using both psychologic methods and drugs. Anyone who proposes to investigate it should do so with a completely open mind and be prepared to review critically any reasonable hypothesis as to its cause.

When the clinical specialties of psychiatry and neurology are viewed in terms of these theories about disease and psychosocial reactions, it is obvious that they overlap. Diseases such as schizophrenia and manic-depressive psychosis, which are cerebral diseases and of interest to neurologists, will for the near future remain in the province of psychiatrists. The latter specialists have the training in psychotherapeutic methods and expertise in neuropharmacology that is needed in the care of such patients. Examples of the intersection of interests between specialties occur regularly in dealing with diseases such as dementia, and in temporal lobe epilepsy, where behavioral and cognitive changes are equally distressing to the patient and family and where drug usage must be supplemented by guidance and explanation of the illness. Finally, and of utmost importance, the psychiatrist must stand as the spokesperson for the medical position on the countless ills related to social and behavioral maladjustments in modern life.

**Psychosomatic Medicine**  It is difficult to appreciate the evolution of psychiatry, particularly in America, without mentioning the impact of psychosomatic medicine on theoretical thinking. Beginning in the 1930s there was great interest in a large category of disease referred to for decades by this term. Included at one time or another were peptic ulcer, mucous and ulcerative colitis, hay fever, asthma, urticaria, angioneurotic edema, essential hypertension, hyperthyroidism, rheumatoid arthritis, amenorrhea, and migraine—diseases in which a stressful life situation or emotional upset appeared to be associated with their development, exacerbation, or prolongation. By extension, certain personality traits were thought to be prevalent in patients who later developed brain diseases, such as Parkinson disease. More than 70 years have passed since these ideas were first promulgated and expressed, an enormous literature followed, but with the establishment of pathetically few unassailable facts for each of them. It became clear that the so-called psychosomatic diseases are not neuroses and, in most instances, a demonstrable pathologic basis has been discovered. Even peptic ulcer, an old psychosomatic favorite, has been traced to a bacterial infection. No proof of psychic causation of any of the psychosomatic diseases has been found. Treatment has been concerned mainly with the relief of physical symptoms and has been directed for the most part by nonpsychiatric specialists. There was never firm evidence that the therapeutic results obtained by psychiatrists were better than those of a competent internist or simply of the passage of time.

This extended application of the concept of psychosomatic disorders is still prevalent. The current societal preoccupation with “stress” as a cause or trigger for all manner of medical and neurologic disease, including disordered function of the immune system (psychoneuroimmunology), is an extension of this tenuous concept.

Interestingly, the terms *psychosomatic* and *psychophysiology* are not listed in the fourth edition of the American Psychiatric Association’s official diagnostic manual, the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*. A few of the disorders originally called *psychosomatic* now appear under the categories of *somatoform disorders* or *psychological factors affecting physical conditions*; these are discussed in subsequent chapters. The reader seeking further information as to the status of psychosomatic or psychophysiological disorders is referred to the review by Rogers, Fricchione, and Reich.

**PLAN OF PSYCHIATRY SECTION**

In the chapters that follow there will be a consideration of the neuroses, the affective disorders, the sociopathies, the schizophrenias, and the paranoid states. The magnitude of these disorders and their clinical and social importance can hardly be overestimated. Some 20 to 30 percent of all individuals will at some period of their lives experience psychiatric
symptoms and seek medical help for them. The headings that guide our exposition of neuropsychiatric illnesses might be questioned, but the justification for their selection is that each can be diagnosed by a competent physician and each diagnosis, once made, can be validated by follow-up studies and treatment based on proper diagnosis can be prescribed. All physicians should know something about these categories of psychiatric disease. Neurologists in particular need to be familiar with them, if only for the purposes of differentiating them from other neurologic diseases and initiating intelligent management but also to discuss intelligently the operation of the diseased brain.

Emphasis throughout these chapters will be on the biologic characteristics and the diagnosis of each state. This approach is in keeping with a significant change in American psychiatry, namely, the development in the 1960s through 1980 of rigorous criteria for the diagnosis of psychiatric disorders. The stimulus for this development can be traced largely to the studies of Mandel Cohen and Paul McHugh and the Washington University group in St. Louis (Feighner, Robins, Guze, and their colleagues and expressed in the monographs of Goodwin and Guze and of Rakoff et al). Many of the diagnostic formulations proposed by these clinicians were adopted, in 1980, by DSM-III (and its several subsequently revised forms). The prevention of suicide, the choice of appropriate therapy, communication with the patient’s family and physician, predictions about the course of the illness (prognosis)—all begin with accurate diagnosis. In addition to their practical clinical value, strict diagnostic criteria are important in psychiatric research.

In forwarding the structural bias of neurologic medicine, we by no means wish to depreciate the importance of psychologic medicine or of psychiatry. Our position on this matter has been fully stated in the preceding pages and needs no further elaboration. Theoretic aspects of personality and psychopathology and symptom formation will be given little space because of our uncertainty about the status of such psychologic mechanisms.

REFERENCES

This page intentionally left blank.
From time immemorial, in every society, it has been realized that there are many troubled individuals who are neither insane nor mentally retarded. They differ from other people in being plagued by feelings of inferiority or self-doubt, suspicion about the motives of others, low energy, inexplicable fatigue, shyness, irritability, moodiness, sense of guilt, and unreasonable worries and fears. They suffer as a result of these feelings or they behave in ways that are upsetting to those around them and to society at large. Yet none of these conditions precludes partaking in the everyday affairs of life, such as attending school, working, marrying, and rearing a family. As these conditions were more carefully documented, the ones that caused an individual much personal distress came to be called psychoneuroses and, later, neuroses, and those that created societal difficulties were called psychopathies and, more recently, sociopathies.

The question of the purity and homogeneity of these mental states has excited a lively polemic in psychiatry for a century. The neuroses as a group appeared to be so diverse as to require subdivision in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders, DSM-IV into no less than seven different types, as elaborated further on. Originally, Freud referred to the neuroses as psychoneuroses, and the subject became enmeshed in psychoanalytic theory. The assumption was that an undercurrent of anxiety arising from unconscious conflict explained all the different types of neuroses as well as the psychopathies. Later, psychiatrists uncommitted to psychoanalytic theory attributed these states to social forces leading to maladaptive behavior from childhood. These notions were not acceptable to biologically oriented psychiatrists, with the result that the term psychoneurosis was expunged from later editions of the DSM and even neurosis was replaced by terms such as anxiety disorders, phobic states, and obsessive-compulsive disorder. These terms are at present applied to any mental disorder with the following characteristics: (1) symptoms that are distressing to the affected individual and regarded by him as unacceptable or alien; (2) intactness of reality testing (the patient’s evaluation of the relationship between himself and the outside world); (3) symptomatic behavior that does not seriously violate social norms, although personal functioning may be considerably impaired; (4) a disturbance that is enduring—not a transitory reaction to stress; and (5) absence of a discernible medical cause or structural disease of the brain. The foregoing definition of the anxiety and allied disorders, or neuroses, has the virtue of being descriptive without committing one to any hypothesis of causation.

The genesis of the neuroses remains elusive. It is generally conceded that such disorders do not arise de novo in otherwise healthy individuals. The antecedents are thought to be abnormalities in personality development, strongly influenced by genetic factors, and possibly molded by stressful events in the life of the individual (Noyes et al). Traits of this nature undoubtedly arise in several individuals from the same family. Thus an informative discussion of such disorders requires a brief digression into the origins of normal personality development and departures from it.

The concept of personality and its development were introduced in Chap. 28. There it was pointed out that the term embraces the totality of a person’s physical and mental attributes, his observable behavior and reportable subjective experience—the sum of which distinguishes one individual from all others. Thus it includes elements of the individual’s character, intelligence, instinctual drives, temperament, sentiments, behavior, motor control, and memories—in short, all forces from within the organism, as well as the reactions to prevailing influences of the environment that govern behavior. The term character is almost synonymous with personality but is less useful in medicine because of its emphasis on interpersonal and ethical aspects and moralistic connotation.

The roots of personality are multiple and deviations from the normal or the average—such as in boldness and timidity, novelty seeking and excitability, level of energy and activity, fearfulness and fearlessness, social adaptability and rigidity or stubbornness, etc.—are already evident in the first months of life. Monozygotic twins are alike (but not absolutely identical) in these respects, even when reared apart. Gesell and his colleagues, in their studies of infants (see Chap. 28), observed individual differences that are clearly innate; each of these characteristics is genetically determined, like intelligence. The personalities that result are as individualistic as fingerprints. One example of a genetic predisposition to a human personality trait, albeit to a limited degree, has been found in the expression of thrill seeking, exploration, and excitability. According to Cloninger and colleagues, pleomorphism of the dopamine receptor gene on chromosome 11 accounts in a small measure for the genetic variability of this personality type. Findings such as these, which have been reproduced by other investigators, suggest that similar polymorphisms contribute to other traits such as anxiety, obsessiveness, etc. The notion, expressed by authors such as Kandel, that genetics will explain a large part of mental function and mental illness sounds reasonable enough, but the data to establish this prediction are far from complete.

Pertinent to the subject matter of this chapter is the assumption that in approximately 15 percent of the general population, certain personality traits are so pronounced as to be distressing to the individual and disturbing to others, even though the patient is not manifestly sociopathic or psychotic. Some of these traits are seen first in infancy and become sources of difficulty during childhood in relation to eating, behavior during play, and school attendance. Psychodynamic explanations abound, but—not based on reproducible evidence—are difficult to validate. They tend to emphasize the resulting psychologic conflict and deemphasize genetic and biologic factors. Therefore, the extent to which these deviations reflect past experience or a genetically predetermined pattern is unsettled.

Another unsolved problem is whether each of the personality types accepted by the American Psychiatric Association is predictive or determinative of a particular type of neurosis or psychosis. In this regard, two broad groups of personality disorders can be recognized. In one group—comprising the paranoid, schizoid, cy-
clothyic, and obsessive-compulsive personality types—there are obvious similarities to major types of psychiatric illness. Thus, among patients who develop paranoid schizophrenia, a considerable number will have had the attributes described under “paranoid personality type.” Similarly, among patients who develop schizophrenia of another type, the history will frequently disclose a preexistent “schizoid” personality. In fact, it may be difficult to judge where the personality disorder left off and the schizophrenic illness began. Similarly, it seems clear from several family studies that the cyclothymic personality is related to manic-depressive disease. Obsessive-compulsive personality is related not only to obsessive-compulsive neurosis, as one might expect, but also to depressive disease.

The defining features of the personality disorders fall short of meeting the diagnostic criteria for the neuroses. Yet, an understanding of these personal peculiarities and their less obtrusive traits may be of great help to the physician. This knowledge makes it possible to appreciate their role as sources of perennial complaint, self-concern, and family discord and to explain a patient’s reactions, which may have interfered with diagnostic and therapeutic procedures during a medical illness.

Personality disorders, like personality itself, are pervasive, enduring, and little influenced by the physician, although often the contacts between physician and patient over many years and repeated reassurance and explanations of how best to cope with difficulties may serve as a stabilizing force. The use of medications to influence some aspect of personality should be avoided unless there is evidence that the peculiarity of personality has developed into a full-blown neurosis. However, one should never underestimate the power of maturation to ameliorate the turmoil of adolescence and to settle the young mind.

THE NEUROSES

Though considered to be the most frequent of mental disturbances, the neuroses are among the least understood. They were established as clinical entities in the late nineteenth century, but there are still major unresolved issues with respect to their nature, classification, and etiology. Descriptively, the neurotic disorders include the following syndromes: (1) anxiety neurosis; (2) phobic neurosis, which includes phobia of illness, social phobia, and agoraphobia; (3) obsessive-compulsive neurosis; (4) hysteria; and (5) hypochondriasis. Former classifications included additional types called neurasthenia (dysthymia or depressive neurosis), which is now considered with the depressive illnesses, and “depersonalization neurosis” (dissociative disorders), which is probably a form of hysterical neurosis. Although each of these syndromes is clinically identifiable and separable when occurring in pure form, experience shows that most patients suffer from symptoms of more than one type and therefore are said to have “mixed neuroses.” In the most recent classifications, all of the neuroses have been again replaced by three broad categories: (1) anxiety disorders (which include panic states, with and without agoraphobia, and the phobic and obsessive-compulsive neuroses); (2) somatiform disorders (comprising hysterical neurosis, or conversion disorder, and hypochondriasis); and (3) dissociative disorders.

It is evident from these and several other attempts at classification that a single definition—one that would satisfactorily explain the attributes of all the neuroses—is still to come. Syndromes as different as hypochondriasis and panic reaction are not likely to lend themselves to a unitary explanation. If there is a central feature of the neuroses, however, it is thought to be anxiety, which runs as a kind of leitmotif through all of them. Even in hysterical neurosis and sociopathy, in which patients seem indifferent to their disabilities, there is often a strong undertone of anxiety.

In an epidemiologic survey sponsored by the National Institute of Mental Health, it was estimated that approximately one-third of the population of the United States, at some point during their lives, have some type of mental disorder. In this survey, disorders related to chronic alcoholism were the most common, followed by anxiety, alterations in mood, and obsessive-compulsive, phobic, conversion, and so-called posttraumatic stress disorders. A different view of the relative frequency of mental disorders was provided by an analysis of 1045 consecutive psychiatric consultations at the New England Center Hospital (now New England Medical Center) during the years 1955 and 1956. In this tertiary referral hospital, the dominant psychiatric syndrome in about 20 percent of patients was an anxiety state.

Other epidemiologic studies have also disclosed a strikingly high incidence of anxiety disorders in the general population (see the review of Winokur and Coryell). Lifetime prevalence figures indicate that at least 11 percent of the population is so affected—i.e., some 25 million persons in the United States. Such information as is available suggests that the incidence of the neuroses is much the same in an urban population (midtown New York) as it is in a rural one (Stirling County, Nova Scotia) indicating that socioeconomic, racial, and cultural factors are of relatively little importance. Furthermore, in times of calamity, such as the bombing of London, the incidence of neurotic symptoms was said not to have increased. Thus one tends to dismiss as an oversimplification the notion that neuroses are merely by-products of life in civilized society or reactions to environmental stress (see also Chap. 24). The symptoms first arise in late childhood, adolescence, and early adult life. Admittedly, neurotic symptoms may be recognized for the first time after this age, but a good clinical rule is to suspect any mental illness that appears for the first time after the age of 40 years to be either a depression or a dementia that is due to degenerative or other organic disease of the brain.

ANXIETY NEUROSI S AND PANIC ATTACKS

The term anxiety neurosis was introduced by Freud in the latter part of the nineteenth century to describe a syndrome consisting of general irritability, anxious expectation, anxiety attacks, somatic accompaniments or equivalents of anxiety, and nightmares. In anxiety neurosis, this symptom complex constitutes the entire illness. However, as indicated earlier, parts of this constellation also appear in several other psychiatric diseases—manic-depressive psychosis, schizophrenia, hysteria, and phobic neurosis. Its closest link is with depression, which it resembles in another respect—namely, there is a strong hereditary factor in both, as pointed out by our colleague, Mandel Cohen in 1940. The term used in DSM-IV is anxiety disorder, of which phobias, obsessive-compulsive disorder, panic attacks, and so-called posttraumatic stress disorder are the important subdivisions.

Clinical Presentation

Anxiety neurosis is a chronic disease, punctuated by recurrent attacks of acute anxiety or panic. The acute attacks are the hallmark of the disease and many psychiatrists are reluctant to make a di-
agnosis of anxiety neurosis in their absence. Because of the clinical features of panic attacks and particularly their episodic nature, which simulates an acute medical condition, they are of special interest to neurologists and general physicians. Fully developed panic attacks are almost as dramatic as seizures. They begin with distressing feelings of dread and foreboding. The patient is assailed by a sense of strangeness, as though his body had changed or the surroundings were unreal (depersonalization; derealization). He is frightened, sometimes by the prospect of imminent death (angor animi) or of losing his mind or self-control. There may be a feeling of smothering. “I am dying,” “This is the end,” “Oh, my God, I’m going,” or “I can’t breathe” are the characteristic expressions of alarm and panic. The heart races, breathing comes in rapid gasps, pupils are dilated, and the patient sweats and trembles. The palpitation and breathing difficulties are so prominent that a cardiologist is often called. Some of our psychiatric colleagues identify breathlessness or a suffocating feeling as central to the diagnosis of panic and will not make the diagnosis without it (some of them also attribute great psychologic meaning to the symptom). The symptoms abate spontaneously after 15 to 30 min, leaving the patient shaken, tense, perplexed, and often embarrassed. There is no element of confusion, and after the episode, there is full memory of the event.

Most anxiety attacks are of lesser severity than the one previously described. The patient complains of faintness, palpitations, or a feeling of postural instability, referred to as dizziness. Breathlessness, vague chest or upper abdominal discomfort, a palpatory feeling as if the heart were beating too hard, and asthenia are other common symptoms. Over 50 years ago Cohen and White listed the following symptoms in order of frequency in the patients they observed: palpitation, 97 percent; easy fatigue, 93 percent; breathlessness, 90 percent; nervousness, 88 percent; chest pain, 85 percent; sighing, 79 percent; dizziness, 78 percent; apprehensiveness, 61 percent; headache, 58 percent; paresthesias, 58 percent; weakness, 56 percent; insomnia, 53 percent; unhappiness, 50 percent.

Many patients experience a constant uneasiness that the spells may occur in public; hence the patient may be fearful of leaving his home lest help not be available should an attack occur (agoraphobia). Except in minor details, it is notable that all the attacks are alike in any one individual. Between attacks, some patients feel relatively well, but many complain of the symptoms of anxiety and asthenia in lesser but persistent fashion.

Hyperventilation is a special though not invariable feature of the anxiety attack. Hyperventilation itself, by reducing the PCO2, will cause giddiness, paresthesias of the fingers, tongue, and lips, and at times frank tetany. However, contrary to what is stated in some textbooks, in only a minority of patients does a 3-min period of commanded deep breathing reproduce the symptoms of an anxiety attack. This maneuver may be used to assist the patient in describing certain aspects of an attack.

Anxiety attacks may occur at infrequent intervals or several times a day. They may occur in situations where there are no easily recognizable sources of fear, as when the patient is sitting quietly at home or has just awakened from sleep. In other instances, a trying or upsetting experience induces an attack, which is nonetheless excessive for the condition that provoked it. In some patients, attacks are brought on consistently by confinement to a closed space (claustrophobia)—an elevator, for example—or by crowded surroundings, as in a church, restaurant, or theater. An anxiety state frequently follows an accident and may, according to Modlin, be a source of ongoing disability. Similar spells of anxiety are also a prominent feature of the postconcussive syndrome (page 864).

The onset of anxiety neurosis is often insidious—feelings of tenseness, vague apprehension, fatigue, weakness, and giddiness having been present for weeks or months before the first panic attack. From the history alone, two patterns of chronic anxiety neurosis are discernible. In one, there is a nearly lifelong history of poor exercise tolerance, little stamina, inability to do heavy physical work or participate in vigorous sports, tenseness, nervousness, and intolerance of crowds, i.e., what had been called neurasthenia. These symptoms often arise during military service and had been designated, since the American Civil War, as neurocirculatory asthenia, “irritable heart,” or “soldier’s heart.” In the other pattern of onset, the patient is vigorous and symptom-free before the anxiety state begins. The latter type usually has its origin in a late-life “anxious depression” that nonetheless may arise on a background of lifelong mild anxiety or obsessiveness.

Most patients with chronic symptoms first consult a physician not with a complaint of “anxiety” but with symptoms referable to the cardiorespiratory system or gastrointestinal system (dyspepsia, loss of appetite, or “irritable colon”). The physical examination between acute attacks yields relatively little of diagnostic value. The common findings, disclosed by the study of Cohen and associates, were slight tachycardia, sighing respirations, yawning, flushed face and neck, tremor of the outstretched hands, and brisk tendon jerks. The patient tends to be restless and abrupt in movement, expressive of an inner uneasiness. During a panic attack, there may be manifest agitation and a tendency to leave the current venue, and blood pressure is invariably elevated.

The onset of both acute and chronic anxiety neurosis is rare before 18 or after 35 to 40 years of age (average age of onset, 25 years). The condition in some series is twice as frequent in women as in men, and there is a high familial incidence. In one study (Wheeler et al) there was a prevalence of 49 percent among the grown children of patients with anxiety neurosis, compared with a prevalence of about 5 percent in the general population. Slater and Shields found that there was a concordance rate of 40 percent in identical twins, compared with 4 percent in dizygotic twins. Among the relatives of index cases, the mothers suffered from anxiety neurosis more often than did the fathers; in the latter, alcoholism was more frequent than in the population at large (Modlin). The pattern of inheritance has not been established, but it most closely approximates that of autosomal dominance with incomplete penetrance.

The course of anxiety neurosis is variable. The symptoms fluctuate in severity without apparent relation to environmental stress. A 20-year follow-up study by Wheeler and associates showed that symptoms of anxiety neurosis were still present in 88 percent but persisted in being moderately or severely disabling in only 15 percent. Most affected patients were able to work and to enjoy a reasonably normal family and social life. Their only liability to further psychiatric illness was to recurrent anxiety neurosis or to later anxious depression whereas so-called psychosomatic illnesses and other psychiatric illnesses did not occur more frequently than in the general population. The life span of patients with anxiety neurosis is not shortened. Those with pure, uncomplicated anxiety neurosis rarely commit suicide.

Etiology and Pathogenesis

Anxiety neurosis has been attributed to a genetic abnormality, to constitutional weakness of the nervous system, to social and psy-
chologic factors, some of which have already been discussed, and, more recently, to certain physiologic and biochemical derangements; but none of these factors provides a completely satisfactory explanation of the primary disorder. The psychodynamic theories that attempt to provide a unified explanation of these diverse neurotic states have been reviewed by Nemiah. The symptoms of an anxiety attack resemble those of fear in many ways, though nearly always the former symptoms are longer in duration and less distinct. The most important difference, however, is that the cause of fear is known to the patient, whereas that of anxiety is not.

On the physiologic and biochemical side, it has been observed that anger provokes an excessive secretion of norepinephrine, whereas fear is accompanied by increased secretion of epinephrine. Actually, fear activates the autonomic nervous system, and the increase in epinephrine is more than counterbalanced by a parasympathetic discharge. Attention has been focused on overactivity of the locus ceruleus and upper brainstem nuclei as the possible anatomic substratum of anxiety (Judd et al). Other studies have implicated serotonergic centers. Evidently, the responsiveness of the autonomic nervous system in these patients remains heightened, and a number of stimuli (cold, pain, muscular effort) may produce abnormal responses in pulse, respiration, oxygen consumption, and work performance. Another interesting abnormality (first noted by Cohen et al) is that the blood lactic acid levels in response to exercise are higher than normal. The presence of these derangements does not necessarily mean that they are causal; they are as likely secondary to other factors such as poor physical condition and apprehension associated with the syndrome. Nevertheless, some investigators have found that infusions of lactic acid can trigger panic attacks in persons with anxiety neurosis (Liebowitz et al). Subsequently, a number of other theories of causation have been proposed based on the reported provocation of panic attacks by a number of different substances—carbon dioxide, yohimbine, gamma aminobutyric acid (GABA), isoproterenol, and others. None provides a comprehensive biological explanation.

Studies correlating cerebral function and blood flow indicate that when panic is induced by an intravenous injection of sodium lactate, there is an immediate increase in blood flow to the cortex of both temporal lobes. In states of fear, the tips of the temporal lobes and the amygdaloid nuclei are known to become activated. In the relaxed period between panic attacks, the right limbic system and the parahippocampal gyrus are abnormally active in some studies. As with the aforementioned biochemical models, these seem to be more reflections of brain activity in response to the psychic experience than they are explanations. Nevertheless, parts of the limbic system are presumably involved in a germinal way in the production and perpetuation of anxiety and its related states. The most extreme but not inconceivable interpretation of anxiety is the James-Lange theory of emotion, which attributes the psychologic experience entirely to the accompanying physical symptoms.

Of potential importance is the finding of a connection between anxiety traits and certain genetic polymorphisms such as one of the serotonin transporter gene on chromosome 17 (Lesch et al). It is estimated that allelic differences on the chromosome contributes perhaps 10 percent to the overall neurotic tendency, and there is an implication that numerous additional genes may participate in a similar way. Others have not found this particular association or have found it only in patients with generalized anxiety but not those with panic attacks. Therefore the precise relationship of this and other genetic abnormalities to neurosis cannot be stated at this moment but a heritable component is undoubted.

Differential Diagnosis

Shorn of the psychologic components of apprehension and fear, the anxiety attack consists essentially of an excessive autonomic discharge. Some of the autonomic symptoms are duplicated by chromaffin tumors, hyperthyroidism, and the menopause. The prominence of chest discomfort and respiratory distress during an acute anxiety attack may be mistaken for myocardial ischemia, in which case the patient is often subjected to a series of studies of cardiac function. Another form of the illness—in which dizziness, a vague difficulty with visual clarity, and fear of losing consciousness are the most prominent features—may be mistaken for a neuro-ologic problem ("panic-vertigo," page 258). In contrast, numerous other symptoms such as headache are relatively infrequent, and the diagnosis should be suspect if headache is a prominent feature. (Chronic headache may be part of chronic anxiety state or anxious depression.) Loss of consciousness, incontinence, and clonic or myoclonic movements do not occur. Other medical diseases that are brought to mind by particular elements of an anxiety state are pulmonary embolism, cardiac arrhythmias, hypoglycemia, hypoparathyroidism, alcohol, drug, and nicotine withdrawal, and especially complex partial seizures. Strict adherence to the diagnostic criteria of these disease states readily permits their differentiation from acute anxiety, but diagnosis may be difficult if the symptoms of anxiety are very brief or persist for hours or days on end.

Of greater importance is the relationship of anxiety neurosis to other psychiatric illnesses, particularly to depression. Symptoms of depression are frequently added to those of anxiety neurosis, and the majority of patients with depression have symptoms of anxiety. Indeed, some psychiatrists believe that anxiety neurosis is accounted for mainly by a variant of depression. As has been mentioned, an anxiety state appearing for the first time after the fortieth year usually proves to be primarily a depression. The uncovering of paranoid symptoms in a patient with an anxiety state should always raise the question of depression, as should the presence of symptoms such as overwhelming fatigue, self-deprecation, and feelings of hopelessness and, of course, ideas of self-destruction. As mentioned, a very small number of patients with a condition diagnosed as pure anxiety neurosis by competent psychiatrists have committed suicide.

Schizophrenia may also begin with prominent anxiety symptoms. Here the diagnosis rests on finding the characteristic thought disorder of schizophrenia, which may emerge only after several interviews. Hysteria may include anxiety symptoms, though they are seldom prominent, as do also phobic and obsessive-compulsive neuroses, but each has other distinguishing attributes.

Treatment

Certain medications, particularly anxiolytics and antidepressants, are highly effective in suppressing panic attacks and creating a sense of well-being. Among these, the benzodiazepine alprazolam (2 to 6 mg/day) is currently favored, but lorazepam and clonazepam are almost as effective and are considered slightly less likely to cause dependence. They are all effective within hours. In mild cases, the benzodiazepines may be used intermittently rather than several times daily, but they tend to be less useful once a panic attack has become established. The panic attacks tend to recur when the medications are discontinued, even after prolonged (6 to 12 months) administration. Attempts to reduce the amount of these medications should be gradual. Tricyclic antidepressants and drugs
that putatively raise serotonin concentrations in the nervous system (selective serotonin reuptake inhibitors, or SSRIs) are also effective to some degree in the prevention of panic attacks and agoraphobia but their onset of action is delayed for weeks. They become useful for symptoms of anxiety that persist for more than several months. The doses are similar to those used to treat depression (see Chap. 57). Buspirone, a specific serotonin 5-HT₁ agonist, has been promoted as effective in the treatment of anxiety and as a surrogate for benzodiazepines, but its benefit has seemed to us to be slight. It is important to point out that during the initial weeks of administration of antidepressants, the underlying anxiety symptoms may worsen and an anxiolytic is usually required until the antidepressant becomes effective. Propranolol, 10 to 20 mg three times daily, or a long-acting form of adrenergic blocker, reduces many of the autonomic accompaniments of anxiety and is useful to many patients, but its effects on the other symptoms are uncertain.

For true anxiety neurosis with panic attacks, psychiatric consultation is valuable. With regard to psychotherapy, behavioral therapy (progressive exposure of the patient to panic-provoking situations) is said to be beneficial, particularly if agoraphobia is a major symptom. Relaxation activities, including biofeedback and meditation, help many patients, although persistence is required in performing these at least once daily and they are less helpful once a panic attack has begun. So-called cognitive-behavioral psychotherapy, which is discussed in relation to the treatment of depression (page 1315), also appears to be useful in the treatment of panic disorder according to Andreasen and Black. A cardiac consultation and some simple tests (electrocardiogram, chest films) may be needed to reinforce the benign nature of the cardiac and respiratory symptoms and to alleviate the patient’s fear of heart disease. These and other current concepts of the treatment of anxiety are discussed by Goodwin and Guze. Anxiety symptoms arising in relation to a particular threatening event in a nonneurotic individual carry the best prognosis.

**PHOBIC NEUROSIS**

In this state, patients are overwhelmed by an intense and irrational fear of some animal, object, social situation, or disease. Though acknowledging that there are no grounds for a particular fear (hence it is not a delusion) and that such provocative stimuli are for the most part innocuous, the patient is nonetheless powerless to suppress it. This disorder was known to Hippocrates, who drew a distinction between normal and morbid fears. Westphal in 1871 was the first to give morbid fears the status of a disease. Women are affected slightly more often than are men.

Unlike an anxiety attack, such a phobia always focuses on a specific object or situation. The patient is chronically fearful of a particular animal or situation and becomes extremely anxious or panic-stricken and incapacitated when placed in a situation that evokes the phobia. These situations are avoided at all costs. For example, it may be impossible for the patient to leave the house or neighborhood unaccompanied—or at all, mingle in a crowd, walk across a bridge, or travel by air. This fear of being in places or situations from which escape might be difficult or extremely embarrassing is spoken of as agoraphobia. (Agoraphobia, however, may be a secondary feature of other psychiatric disorders, the most frequent being anxiety with panic attacks as already mentioned.) The most common phobia is probably claustrophobia (the fear of being confined in a close space, such as an elevator or a magnetic resonance scanner). Other phobias, as remarked earlier, are those of open (agoraphobia), closed, or high places, dogs, cats, insects, dirt, sprays and other contaminants, air travel, acquired immunodeficiency syndrome (AIDS), cancer, insanity, and death. Feelings of helplessness, pessimism, and despondency, the hallmarks of a depressive illness, result after years of phobic suffering. Often there are obsessive-compulsive tendencies as well, and some patients are hypochondriacal. Phobias are essentially obsessive fears and are somehow allied with this latter category of neurosis. The present authors have observed a number of patients whose phobic (or obsessive-compulsive) neurosis became greatly exaggerated as an endogenous depression developed. Recovery from the depression returned them to their earlier and milder phobic state. All of these features suggest a linkage between neuroses and depression.

**OBSESSIVE-COMPULSIVE NEUROSIS**

Like the pure phobic states, a neurosis dominated by obsessions and compulsions is relatively rare, occurring in less than 5 percent of patients seeking help in a psychiatric outpatient clinic, but they can be extremely disabling. Minor compulsions (for example, not stepping on cracks in the sidewalk), like minor phobias, are common in children, cause little or no distress, and tend to disappear in later life. A few, such as rechecking a locked door or a gas stove, may persist throughout life. Also, certain habits and rigid, obsessional ways of thinking, stubbornness, extreme punctuality, and excessive attention to detail are frequent and persistent but excite little attention medically unless they interfere with a diagnostic procedure or the treatment of a medical disease.

**Obsessive-compulsive neurosis, or disorder, as it is now designated, begins, as do the other neuroses, in adolescence or early adult years, although treatment may not be sought until middle age is reached. The two sexes are equally affected. The onset is usually gradual and often cannot be accurately dated, but in some cases it is precipitated by a particular event in the patient’s life, such as the death of a relative. The family history often discloses a high incidence of obsessional or phobic personality in other members. In some, but not all, instances, the obsessive-compulsive neurosis is engrafted onto a personality in which rigidity, inflexibility, and lack of adaptability are prominent. There is always a prevailing undercurrent of insecurity and anxiety.**

**Obsessions** are defined as imperative and distressing thoughts and impulses that persist in the patient’s mind despite a desire to resist and to be rid of them. They take various forms; the most common are intellectual obsessions, in which phrases, rhymes, ideas, or vivid images (these are often absurd, blasphemous, obscene, and sometimes frightening) constantly intrude into consciousness; impulsive obsessions, in which the mind is dominated by an impulse to kill oneself, to stab one’s children, or to perform some other objectionable act; and inhibiting obsessions, in which every act must be ruminated upon and analyzed before it is carried out—a state that was cleverly called doubting mania. Every effort at distraction fails to rid the patient of the obsessive thought. It engulfs the mind, rendering him miserable and inefficient. Probably the most disturbing obsessions are the impulsive ones, in which patients constantly struggle with the fear that they will put some terrible thought into action. Even as they tell of the obsession, they reveal a severe underlying anxiety and seek reassurance that they will not yield to it. Fortunately, such patients rarely obey their pathologic impulses. Phobias, as mentioned earlier, are considered
by some authorities to be essentially obsessive fears and may be included in this category of neurosis.

Compulsions are acts that result from obsessions. These are single acts or a series of acts (rituals) that the patient must carry out in order to put his mind at ease. Examples are repeated checking of the gas jets or the locks on doors, adjusting articles of clothing, repeated hand washing, using a clean handkerchief to wipe objects that have been touched by others, tasting foods in specific ways, touching or arranging objects in a particular sequence, etc. In general, the most common of these obsessions and compulsions center around contamination concerns that lead to repeated hand washing or bathing. Other obsessions and compulsions can be identified as clusters that derive from the above-mentioned concern about harm to oneself or to others and consequent checking on others, or praying or requesting constant reassurance that a harmful act will not be carried out. Less common clusters involve excessive focus on symmetry, precision, and ordering, and on saving and hoarding.

Certain motor disturbances—namely, habit spasms or tics—are, in a sense, motor compulsions. They consist of repetitious movements of the shoulders, arms, hands, and certain of the facial muscles (see Chap. 6). One feature that separates quasivoluntary tics from involuntary movements of extrapyramidal type is the patient’s feeling that the tics must be carried out to relieve an inner tension. Unlike compulsions, however, tics are not usually based directly on obsessive thoughts—except perhaps the Gilles de la Tourette syndrome, in which multiple tics are combined with compulsive utterances, often offensive ones (see later).

In all these obsessions and compulsions and in the phobias, patients recognize the irrationality of their ideas and behavior yet are powerless to control them, much as they desire to do so. It is this insight into the obsessional experience and the struggle against it that distinguishes obsessions from delusions.

These patients often suffer from typical anxiety attacks. After the condition has persisted for a time, they may become depressed. Fatigue, anorexia, and general lack of interest, which are often present, are probably related to the secondary effects of anxiety and depression.

Mechanisms of Obsessive Neuroses

For many years a number of psychoanalytic conceptualizations held sway of obsessional neurosis as the product of intrapsychic conflicts. Only relatively recently has a neurobiologic model been advanced. These are largely derived from the findings of functional imaging, which have been quite consistent. Positron emission tomography has demonstrated increased metabolic activity in the orbitofrontal cortex, cingulate, and, to a lesser extent, striatum of affected patients. The orbitofrontal cortex and amygdala were reported to be shrunken in other cases. However, in a study of 13 patients who developed elements of obsessiveness and compulsive disorder after incurring focal brain lesions, Berthier et al found lesions in diverse loci, including the cingulate, frontal, and temporal cortices as well as the basal ganglia. Two of the most accurately localized lesions in their series were a hamartoma of the right parahippocampal gyrius and an infarction in the posterior putamen. The presence of brain injuries and seizure disorders in other of their patients made a precise localization more problematic.

Additional insight into acquired obsessive-compulsive disorder may be obtained from the many cases in which striatal damage is linked to this type of behavior. One such entity is a poststreptococcal tic disorder termed PANDAS (pediatric autoimmune psychiatric disorders associated with streptococcal infections, page 96). This disorder is presumably related to another extrapyramidal condition, Sydenham chorea, in which tics and similar movement disorders as well as obsessive behavioral abnormalities have long been known to coexist. Functional imaging studies in patients with PANDAS have yielded variable findings, but generally there has been increased activity in the caudate nucleus and orbitofrontal cortex in temporal association with the patient’s compulsive thoughts. The neurochemical alterations in obsessive-compulsive disorder have been studied but most of the conclusions have been based on the responses to medications, notably to the serotonin reuptake inhibitors as noted further on. These agents are found to be of therapeutic benefit, as are stereotactic neurosurgical lesions in the cingulate gyri (see further on).

The Gilles de la Tourette syndrome of multiple tics, including vocal ones, beginning in childhood or adolescence and lasting more than a year, also bears a resemblance to obsessive-compulsive disorder. The two conditions often appear together; more than half of Tourette patients have obsessive-compulsive disorder. Both occur in a pattern of inheritance that is close to an autosomal dominant trait with incomplete percent penetrance (Kurlan). Because dopamine antagonists are beneficial in the management of the Tourette syndrome, a number of etiologic hypotheses revolve around serotonergic and dopaminergic neurotransmitter systems (Baxter; Behar et al). More extensive comments on the Tourette syndrome are to be found on page 95.

Treatment

Treatment is best left to the psychiatrist. At least there should be a trial of therapy using behavioral modification techniques. In the case of phobic neurosis, the aim of such treatment is to reduce the patient’s fear to the extent that exposure to the phobic situation can be tolerated. A popular form of therapy is systematic desensitization, which consists of increasing and graded exposure of the patient to the object or situation that arouses the fear. Psychotherapy, if undertaken, need not be intensive, consisting instead of repeated explanation, reassurance, and guidance in dealing with symptoms. As with phobic neurosis, several reports have indicated that compulsive rituals can often be abolished by the techniques of behavior therapy. Much in vogue is cognitive-behavioral psychotherapy alluded to earlier and discussed in the next chapter (page 1315). This too is best left to the experienced psychiatrist.

Certain medications, particularly the SSRI types such as fluoxetine, are considered to be very effective forms of therapy—abolishing or greatly reducing obsessions and compulsions in more than half the patients. The less-selective agent, clomipramine, is also highly effective, as were more commonly used tricyclic antidepressants in the past, but clomipramine is not nearly as well tolerated as are the conventional SSR1 drugs (see review by Stein).

Finally, it should be mentioned that cingulotomy has produced symptomatic improvement in both phobic and obsessional neuroses and was at one time considered a reasonable procedure. This measure, if it is to be used at all, should be considered only as a last resort in exceptionally severe cases in which the patient has failed to respond to all other methods of medical and behavioral treatment and is totally disabled. Perhaps the implantation of a reversible electrical stimulating electrode in this same region is a sensible area for future investigation. This and other surgical approaches to these illnesses has been reviewed by Greenberg and colleagues. They acknowledge that few adequate trials have been conducted.
and it should be pointed out that most of the surgical series they discuss took place well before the modern era of psychopharmacology.

**Hysteria (Briquet Disease; Somatization Disorder)**

Although hysteria has been known since ancient times, many writers credit the first description of the syndrome (on somewhat uncertain grounds) to the French physician Briquet in 1859. Later, Charcot elaborated certain manifestations of the disease, particularly those with a theatrical aspect, and interested Freud and Janet in the problem. Charcot demonstrated that the symptoms could be produced and relieved by hypnosis (mesmerism). Janet postulated a *dissociative state* of mind to account for certain features such as trances and fugue states, a term which has reappeared in modern psychiatry. Freud and his students conceived of hysterical symptoms as a product of “ego defense mechanisms,” in which psychic energy, generated by unconscious sexual conflicts, was converted into physical symptoms. This latter concept was widely accepted, to the point where the term *conversion* became incorporated into the nomenclature of the neuroses and the terms *conversion symptoms* and *conversion reaction* came to be equated with the disease hysteria. In the present authors’ opinion, the term *conversion*, if it is used at all, should refer only to certain unexplained symptoms, such as amnesia, paralysis, blindness, and aphonia, that mimic neurologic disease. We see no merit in the dichotomy, based on unsubstantiated psychodynamic theory, of a conversion type as separate from a dissociative type of hysteria, as claimed by the DSM classification. Nemiah, who is in other respects partial to the psychoanalytic interpretation, agrees. Also in our view, the term *hysteria* is best reserved for a *disease* that is practically confined to women and is characterized by a distinctive age of onset, natural history, and certain somatic symptoms and signs, which typically include “conversion symptoms,” dissociative reactions, or states of “multiple personality.”

In clinical neurology one encounters two types of hysteria or neurologic signs with no possible explanation in disease of the nervous system: (1) a chronic illness marked by multiple and often dramatically presented symptoms and somatic abnormalities of “classic hysteria” for which no cause is evident, almost limited to girls and women, and (2) an illness predominantly of men but also of women, who develop physical symptoms or remain inexplicably disabled for the purpose of obtaining compensation, influencing litigation, avoiding military duty or imprisonment, etc. This latter state is called *compensation neurosis, compensation hysteria*, or *hysteria with sociopathy*, in other words, malingering.

**Classic Hysteria**

This is a neurosis of sorts, which accounts for 1 to 2 percent of admissions to a neurologic service and a greater number of out-patient visits. It usually has its onset in the teens or early twenties, almost exclusively in young women; a very few cases begin before puberty. Once established, the diagnosis remains unchanged over many years but the symptoms recur intermittently, though with reduced frequency, throughout the adult years even to an advanced age. No doubt there are cases of lesser severity in which symptoms occur only a few times or perhaps only once, just as there are mild forms of other diseases. The patient may be seen for the first time during middle life or later, and the earlier history may not at first be forthcoming. Careful probing almost invariably reveals that the earliest manifestations of the illness had appeared before the age of about 25 years.

Other important data are also revealed by eliciting a careful past history. During late childhood and adolescence, the normal activities of the patient, including education, had often been interrupted by periods of ill-defined illness. In the past, rheumatic fever, and in the current era, some obscure disease may have been suspected. Later in life, problems in work adjustment and marriage are frequent. Notable in many cases is a high incidence of marital incompatibility, separation, and divorce. The patient’s life history is punctuated by symptoms that do not conform to recognizable patterns of medical and surgical disease. For these ailments, many forms of therapy including surgical operations will have been performed. In the past, rarely had adult life been reached without at least one abdominal operation, which was usually done because of vague abdominal pain, persistent nausea and vomiting, or an obscure gynecologic complaint. Often the indications for the surgical procedures were unclear; moreover, the same symptoms or others often recurred to complicate the convalescence. The biographies of these patients are replete with disorders that center about menstrual, sexual, and procreative functions. Menstrual periods may be painfully prostrating, irregular, or excessive. Sexual intercourse may be painful or unpleasant. Pregnancies may be difficult; the common vomiting of the first trimester may persist all through the gestational period, with weight loss and prostration; labor may be unusually difficult and prolonged, and all manner of unpredictable complications are said to have occurred during and after parturition.

Hysteria is, then, a polysymptomatic disorder, involving almost every organ system. The most frequent symptoms that were reported by Purcell and colleagues during a study of 50 unmistakable cases of hysteria (as compared with a control group of 50 healthy women) included the following: headache, blurred vision, lump in the throat, loss of voice, dyspnea, palpitation, anxiety attacks, anorexia, nausea and vomiting, abdominal pain, unusual food allergies, severe menstrual pain, urinary retention, sexual indifference, painful intercourse, paresthesias, dizzy spells, nervousness, and easy crying.

The mental examination of the patient with hysteria demonstrates a number of characteristic findings. There is a lack of precision in relating the details of the illness. Questions regarding the chief complaint usually elicit a vague reply or the narration of a series of incidents or problems, many of which prove to have little or no relevance to the question. Memory defects (amnesic gaps) are usually demonstrated while the history is being taken; the patient appears to have forgotten important segments of the history, some of which she had clearly described in the past and are part of the medical record. The description of symptoms may be dramatic and exaggerated and not in accord with the facts as elicited from other members of the family. Often, a rather casual demeanor is manifest, the patient insisting that everything in her life is quite normal and controlled, when, in fact, her medical record is checkered with instances of dramatic behavior and unexplained illness. This calm attitude toward a turbulent illness and seemingly disabling physical signs is so common that it has been singled out as an important characteristic of hysteria, *la belle indifference*. Other patients, however, are obviously tense and anxious and report frank anxiety attacks; or the patient may appear to be putting on an act, and demanding constant attention. Emotional reactions are superficial and scenes that are disturbing to others are quickly forgotten. Claims of early-life sexual abuse are common and often prove to
be imagined, but a valid history of such abuse is frequent enough in our experience to play a role in the genesis of some cases (see further on).

There are no pathognomonic findings. Although many have commented on the rather youthful, girlish appearance and coquettish (“seductive”) manner of the patients, these by no means characterize all patients. The abdomen may be diffusely and exceedingly tender but without other signs of abdominal disease. The so-called stigmata of hysteria—i.e., corneal anesthesia; absence of gag reflex; spots of pain and tenderness over the scalp, sternum, breasts, lower ribs, and ovaries—are often suggested by the examiner and are too inconsistent to be of much help in the diagnosis. The variation and pleomorphism of the physical signs are limited only by the patient’s ability to produce them by voluntary effort. Accordingly, symptoms and signs that are beyond volitional control should not be accepted as manifestations of hysteria. Sometimes the patient’s physical signs are an imitation of those of another member of the family (“folie a deux”) or are evoked by a stressful event in the patient’s personal life. However, this may not be disclosed at the time of the first examination.

Special Neurologic Syndromes of Hysterical Origin

A few hysterical syndromes occur with regularity and every physician may expect to encounter them. Most are neurologic in nature. They constitute some of the most puzzling diagnostic problems in medicine.

Hysterical Pain This may involve any part of the body: generalized or localized headache, “atypical facial pain,” vague abdominal pain, and chronic back pain with cymbotocmora are the most frequent and troublesome. In many of these patients the response to analgesic drugs has been unusual or excessive, and some of them are addicted. The hysterical patient may respond readily to a placebo as though it were a potent drug, but it should be pointed out that this is a notoriously unreliable means of distinguishing hysterical pain from that of other diseases. A greater error is to mistake the pain of osteomyelitis or visceral tumor—before other symptoms have developed—for a manifestation of hysteria. There are several helpful diagnostic features of hysterical pain: (1) the patient’s inability to give a clear, concise description of the type of pain; (2) the location of the pain does not conform to the pattern of pain in the familiar medical syndromes; (3) the dramatic elaborations of its intensity (speaking in inflated metaphors—“like a giant knife stabbing”) and its effects on the body (“tearing my limb off”); (4) its persistence, either continuous or intermittent, for long periods of time; (5) the assumption of bizarre attitudes and postures; and, most important; (6) the coexistence of other clinical features or previous attacks of hysterical nature.

Hysterical Vomiting This is often combined with pain and tenderness in the lower abdomen and results in unnecessary appendectomies and removal of pelvic organs in adolescent girls and young women. The vomiting often occurs after a meal, leaving the patient hungry and ready to eat again; it may be induced by unpleasant circumstances. Some of these patients can vomit at will, regurgitating food from the stomach like a ruminant animal. Vomiting may persist for weeks with no cause being found. Weight loss may occur, but seldom to the degree anticipated. As remarked earlier, the usual first-trimester vomiting of pregnancy may continue throughout the entire 9 months, and occasionally pregnancy will be interrupted because of it. Anorexia may be a prominent associated symptom and must be differentiated from anorexia nervosa—bulimia, another closely related disease of young women (page 1304).

Hysterical Seizures, Trances, and Fugues These conditions seem to be less frequent than in the days of Charcot, when la grande attaque d’hystérie was often exhibited before medical audiences. Nevertheless, such attacks do occur and must be distinguished from cerebral cortical seizures and catalepsy. To witness an attack is of great assistance in diagnosis. The lack of an aura, initiating cry, hurtful fall, or incontinence; the presence of peculiar movements such as grimacing, squirming, thrashing and flailing of the limbs, side-to-side motions of the head, and striking at or resisting those who offer assistance; the retention of consciousness during a motor seizure that involves both sides of the body; the long duration of the seizure, its abrupt termination by strong sensory stimulation, lack of postictal confusion, and failure to produce a rise in creatine kinase—are all typical of the hysterical attack. Sometimes hyperventilation will initiate an attack and is therefore a useful diagnostic maneuver. Both epilepsy, particularly of frontal-lobe type, and hysteria may occur in the same patient, a combination that invariably causes difficulty in diagnosis.

Hysterical trances or fugues, in which the patient wanders about for hours or days and carries out complex acts, may simulate temporal lobe epilepsy or any of the conditions that lead to confusional psychosis or stupor. Here the most reliable point of differentiation comes from observation of the patient, who, if hysterical, is likely to indicate a degree of alertness and promptness of response not seen in temporal lobe seizures or confusional states. Following the episode, an interview with the patient—under the influence of hypnosis, strong suggestion, or midazolam or amobarbital—will often reveal memories of what happened during the episode. This helps to exclude the possibility of an epileptic spell.

Hysterical Paralyses, Gait, Sensory Loss, and Tremors Hysterical palsies may involve an arm, a leg, one side of the body, or both legs. If the affected limb can be moved at all, muscle action is weak and tremulous. Movements are slow, tentative, and poorly sustained; often it can be demonstrated that the strength of voluntary movement is proportional to the resistance offered by the examiner, thus imparting a “give-way” character (page 52). One can detect by palpation that agonist and antagonist muscles are contracting simultaneously holding the limb in place rather than opposing the examiner, and when the resistance is suddenly withdrawn, there is no follow-through or rebound, as is normally the case. Other indicators have been devised to demonstrate inconsistencies with normal physiologic principles and a purposive lack of cooperation. These are elaborated in articles by Stone, Zeman, and Sharpe. The discrepancies are usually found by testing an agonist, antagonist, or fixator movement while the patient is focused on making an effort with another group of muscles (e.g., the Hoover sign, see page 52). Muscular tone in the affected limbs is usually normal, but slight resistance may sometimes be found. A seeming lack of effort and the absence of full compliance with the examiner’s requests during the testing of muscle strength, while common in hysterical patients, is not confined to them; one encounters such findings not infrequently during the examination of suggestible but nonhysterical patients who harbor a neurologic disease.

Walking and standing may be impossible (astasia-abasia) or
the gait may be bizarre with collapsing legs that bring the patient to a squat, or there is a “skating” gait in which one foot is pushed ahead of the body, and other forms that are easily recognized as inconsistent with the makings of the nervous system in disease (page 107). Weakness and poor balance are combined elements in both the quadriparetic and hemiparetic forms. In Keane’s informative series of 60 cases of hysterical gait, the hemiparetic and monocular forms were twice as frequent as the quadriparetic. The gait disorder is sometimes difficult to describe because of its variability. Sudden falls without voluntary protective movements and inconsistencies of balance are helpful features. Other features are discussed in Chap. 7 on gait disorders. Difficulty in walking and moving the legs while seated is, of course, not unique to hysteria; it also occurs in so-called frontal lobe gait apraxia and in ataxia from midline cerebellar lesions and in hydrocephalus. In the most remarkable and recalcitrant cases, maintenance of the limbs in a rigid or dystonic posture for a long time may result in a bed-bound, crippled state with severe flexion pseudocontractions of the limbs. We have seen one such case of 18 years duration. The tendon reflexes are usually normal if they can be tested, but with hysterical rigidity and contractures, the abdominal and plantar reflexes may be suppressed.

Anesthesia or hypesthesia is almost always inadvertently suggested by the physician’s examination. Seldom is sensory loss a spontaneous complaint, although “numbness” and paresthesias are not uncommon in hysterics. The sensory loss may involve one or more limbs below a sharp line (stocking and glove distribution), or may involve precisely one half of the body, or vibratory sense may be lost over precisely one half of the skull (a test favored to demonstrate hysterical hemianesthesia). Touch, pain, taste, smell, vision, and hearing may all be affected on that side, which is an anatomic impossibility from a single lesion. Other aspects are discussed in Chap. 9.

The sometimes-stated notion that hysterical paralysis and sensory deficits are more common on the left side is probably untrue according to Stone and colleagues.

The features of hysterical tremor have been described on page 84. To be emphasized are the cessation of tremor with distracting tasks—e.g., complex finger movement patterns on the side opposite the tremor (such as touching the fourth, second, and fifth fingers in sequence rapidly), or reflexation of the eyes on a target, or walking on the outside of the heels. The ability of the examiner to “chase” the tremor to proximal or distal parts of the limb by holding and immobilizing other parts is highly characteristic. Also a fairly dependable sign is worsening of a tremor with loading, that is accomplished by placing a heavy object in the patient’s hand (most basal ganglionic and cerebellar tremors are muted by this maneuver).

Hystericl Blindness (See page 219) This dramatic event may affect one eye or both and may be coupled with hemiparesis or appear in isolation. The symptoms usually develop suddenly, often after an altercation or other emotionally charged event. The patient stares straight ahead blandly when undisturbed but may squint or move the head as if straining to see when asked to view an object. Some such individuals can reduce reflexive blinking in response to a visual threat. The psychic nature of the problem may be recognized by a nurse who observes the patient reaching for a cup or for the phone. The preservation of vision is confirmed by the presence of normal pupillary reflexes and of optokinetic nystagmus, although one occasionally encounters a patient who has learned to suppress the latter response as well. A mirror passed slowly in the patient’s central vision often engages eye movements. Other similar maneuvers are favored by different examiners. The presence of visual evoked responses also confirms the intactness of retino-occipital connections. The patient expresses little concern about her condition, which is usually short-lived. Cortical blindness and variants of the Balint syndrome (pages 404 and 406) from bioccipital infarcts are the main diagnostic considerations.

Convergence spasm, occurring as an isolated phenomenon, is practically always of hysterical nature (page 226).

A related phenomenon involves the self-administration of mydriatic eyedrops by health care personnel. The patient arrives on the emergency ward complaining of reduced vision (expected) or with headache and claiming to have an intracranial mass. This behavior is perhaps more sociopathic (or malingering) than hysterical.

Hysterical Amnesia Patients brought to a hospital in a state of amnesia, not knowing their own identity, are usually hysterical females, or sociopathic males involved in a crime. Usually, after a few hours or days, with encouragement, they divulge their life history. Epileptic patients or victims of a concussion, transient global amnesia, or acute confusional psychosis do not come to a hospital asking for help in establishing their identity. Moreover, the complete loss of memory for all previous life experiences by patients who are otherwise able to comport themselves normally is not observed in any other condition.

In the Ganser syndrome (amnesia, disturbance of consciousness, and hallucinations) patients pretend to have lost their memory or to have become insane. They may act in an absurd manner, simulating the way they believe that an insane or demented person would act, and give senseless or only approximate answers to every question asked of them (calling the color red, blue or answering five for two plus two).

Hysteria in Men (Compensation Neurosis in Men and Women) As stated earlier, symptoms of the same nature as those in hysteria do occur in men, most often in those trying to avoid legal difficulties or military service or attempting to obtain disability or pension payments, or, compensation following injury. Sociopaths may also present with this type of illness. Unless such a motivating factor can be identified, the diagnosis of hysteria in the male should be made with caution. In compensation neurosis, as in the classic form of hysteria, multiple symptoms are reported; many of the symptoms are the same as those listed under female hysteria. Or the patient may be monosymptomatic (e.g., “seizures”) and the symptoms, particularly chronic pain, may be confined to the neck, head, arm, or low back. The description of symptoms tends to be lengthy and circumstantial, and the patient fails to give details that are necessary for diagnosis. A tangible gain from the illness may be discovered by simple questioning. This is usually in the form of monetary compensation, which, surprisingly, is sometimes less than that which the patient could earn if he returned to work. Most such patients are actively engaged in litigation when first seen. Another interesting feature is the frequency with which the patient expresses extreme dissatisfaction with the medical care given him; he is often hostile toward the physicians and nurses. Many of these patients have already been subjected to an excessive number of hospitalizations, and rather dramatic mishaps have allegedly occurred in carrying out diagnostic and therapeutic procedures. The majority have been previously suspected of malingering.
Women who suffer injury at work or are involved in auto accidents may exhibit the same symptoms and signs of compensation neurosis as men but in our experience, do so infrequently.

**Etiology and Pathogenesis**  
Psychoanalytic theory, which holds that both conversion and dissociative symptoms are based on particular psychodynamic mechanisms, is impossible to affirm or refute. While subject to some question of fabricated recall, we have been impressed at the high rate of childhood sexual abuse reported by women with severe monosymptomatic cases of hysteria or fugue states. This conforms to some extent with psychoanalytic views but may not apply in classic hysteria. Sociologic and educational factors are probably important, for it has been observed that hysterical women as a group tend to be less intelligent and less educated than nonhysterical women. A genetic causation must also be considered. Family studies have disclosed that about 20 percent of first-degree relatives of female hysterics have the same illness, an incidence 10 times that in the general population. This supports the idea that hysteria is a disease and not merely a surfacing of a basic personality disorder (see Goodwin and Guze).

Whether conversion symptoms are consciously produced by the patient or arise unconsciously, without the patient’s awareness, is a question that has been debated endlessly without resolution. Babinski attributed the symptoms to hypersuggestibility. In fact, he defined hysteria as an illness whose symptoms could be induced (and removed) by suggestion. There is strong evidence to support this idea, since most patients can be readily hypnotized and their symptoms temporarily eliminated by this procedure, or by an interview and examination under the influence of midazolam. The present authors place great weight on the importance of hypersuggestibility, in keeping with earlier studies that emphasized these patients’ unusual susceptibility to suggestion and hypnosis. Interesting in this regard were the observations of Charcot’s students, that on their wards the patients’ symptoms disappeared in his absence.

Some insights can be obtained from studies of functional imaging in hysterical paralysis (see also Chap. 3). In general, the contralateral prefrontal cortex is suppressed when the patient with hysteria attempts to move a limb, suggesting to Spence and colleagues a “choice” of an active attempt not to move the limb. However, the pattern of activation was quite different from volunteers who purposefully feigned paralysis and who did not demonstrate such reduced prefrontal activity.

As pointed out by Carothers and by Guze and colleagues, hysteria and sociopathy are closely related. Hysteria is a disease of women and sociopathy mainly of men. As restated by Cloninger and colleagues, they may constitute expressions of a single underlying variable. This relationship is also supported by family studies. First-degree male relatives of hysterical women have an increased incidence of sociopathy and alcoholism; among first-degree female relatives of convicted male felons, there is an increased prevalence of hysteria. Moreover, careful histories of sociopathic girls reveal that many of them develop the full syndrome of hysteria. Women felons often present a mixed picture of hysteria and sociopathy, according to Cloninger and Guze.

**Diagnosis**  
The characteristic age of onset; the longitudinal history of recurrent multiple complaints, as outlined earlier; the attitude of the patient and the manner of presenting her symptoms; the incongruity of affect and clinical state; the discrepancy between the neurologic deficit and the signs on examination; the impossibility of explaining the patient’s signs on an anatomic or physiologic basis; and the absence of symptoms and signs of other medical and surgical disease will permit an accurate diagnosis in the majority of cases. Certain tests designed to reveal normal functioning of a limb, of vision, and of gait have been mentioned.

There is a significant overlap of hysteria and other medical and neurologic diseases. On record are numerous studies in which patients with an initial diagnosis of hysteria by general physicians were followed for many years. Up to one third of them (less in most series) turned out eventually to have an “organic condition” which, in retrospect, explained the initial symptoms (Couprie et al). This emphasizes that the original clinical diagnosis of hysteria is often erroneous. When the diagnostic criteria in these cases are closely analyzed, it becomes apparent that the diagnosis was made solely by the “discrepancy method”—i.e., the patient’s symptoms or signs were not deemed to be credible manifestations of disease, based mainly on the clinical experience of the examiner. Of course, this assumes that the examiner has a wide experience; unfortunately for the novice, many syndromes are unknown or incomprehensible.

However, when diagnosis is based on the totality of the clinical picture and not on the “discrepancy method,” it can be quite accurate. The physician can be further reassured that in follow-up studies of patients with so-called conversion disorder (exclusive of pseudoseizures), virtually none develop a neurologic lesion that in retrospect was related to the initial episode as for example in the study by Stone and colleagues. It is of interest that in the series cited, most patients had persistent functional disability from their conversion symptoms, even a decade later.

So-called projective tests (the Rorschach and Thematic Apperception Tests), which for a time were popular with dynamic psychiatrists, are not helpful in diagnosis and are now used very little. The presence of extreme suggestibility and the tendency to dramatize symptoms as measured by one part of the Minnesota Multiphasic Personality Inventory and other psychometric tests is helpful in diagnosis but not pathognomonic of the disease; these traits appear under certain conditions in individuals who never develop hysteria.

Finally it should be reemphasized that single bouts of isolated hysterical paresis, blindness, and anesthesia are quite common in neurologic practice and do not presage a chronic hysterical illness. The same is true for transient neurologic signs exhibited during the course of the examination, mainly pertaining to unusual or drifting sensory loss or asthenic weakness of a limb.

**Treatment of Hysteria**  
This may be considered from two aspects: the correction of the long-standing basic personality defect and relieving the recently acquired physical symptoms. Little or nothing can be done about the former. Psychoanalysts have attempted to modify it by long-term reeducation, but their results are uninterpretable, and there are no control studies for the few reports of therapeutic success. Many psychiatrists are inclined to regard the female with hysteria who has a lifelong history of ill health as having a severe personality disorder—i.e., sociopathy. In other, less severe cases and especially in those in whom hysterical symptoms have appeared under the pressure of a major crisis, explanatory and supportive psychotherapy appears to be helpful, and the patients have been able thereafter to resume their places in society.

The acute symptoms can usually be mitigated by persuasion...
CHAPTER 56 THE NEUROSES AND PERSONALITY DISORDERS

and demonstration. One tactic is to treat the patient as though she has had an illness and is now in the process of recovering. The earlier this is done after the development of symptoms, the more likely they are to be relieved. Sometimes a single symptom such as hemiparesis or tremor can be halted by a particular maneuver and this demonstration suffices to begin recovery. In chronically bedridden patients, strong pressure to get out of bed and resume function must be applied. Compensation and litigation neuroses are quite difficult to treat, and settlement of the patient’s claim (“the green poultice”) is usually necessary before the symptoms subside.

Several approaches to discussing the symptomatology with the patient have been suggested. At one extreme is a confrontative approach in which the patient is told the symptoms are psychologic, or “in your head.” We have found this to be counterproductive and almost always to provoke an angry response that does not aid clinical improvement. On the other extreme is complete avoidance on the part of the physician, an approach that is almost as unproductive. We prefer to ask the patient if the symptoms can in some way be the result of “stress” or an upsetting recent experience. On occasion, in private we will inquire about childhood sexual abuse and often get an affirmative response from the patient, with later confirmation by a spouse or sibling. Next comes nonjudgmental but firm reassurance that there is no serious disease. We have found it very useful to list the diseases that have been excluded by examination and testing: brain tumor, stroke, amyotrophic lateral sclerosis, multiple sclerosis, etc. This often evokes an acknowledgment by the patient that one of the diseases had been a preoccupying concern. We then indicate, without using psychologic terms, that the brain may at times adopt certain patterns of behavior that do not reflect structural damage, and furthermore, these patterns can be unlearned with physical therapy and time as described below.

That the patient’s response to these conversations varies widely is not surprising. One group seems not to mind and to be relieved by the expression of concern and reassurance that there is no dangerous disease at the root of the problem. They can be sent to a physical therapist and may do well in the short run. Another group is indignant and not likely to consult the physician again; several have refused to pay the doctor’s bill. Some have objected to the explanation based on their own view, often derived from research on the internet and with similarly afflicted persons, that Lyme disease, chronic viral infection, environmental toxins, allergies, etc., are to blame. A few of these cases have the flavor of a delusion. All that the physician can offer here is an openness to see and reexamine the patient in several months; “cure” has no meaning in these instances and there is a great likelihood that such individuals will see a long line of doctors.

Persuasion and suggestion, both direct and indirect, should be employed as already noted. Illustratively, the patient should be repeatedly encouraged, told that she is improving, urged to resume work or other duties, and continue participation in routine activities. Medication should be withheld. Some of our best results have been obtained by indicating that the neurologic symptoms are a “constitutional” weakness that can be overcome by physical and other therapies. Once the current neurologic disorder has disappeared, it may be helpful to counsel the patient in ways to prevent its recurrence. Family members should be given the same explanation. A regimen of physical therapy should be instituted, utilizing an experienced therapist and setting simple goals for success. Every subsequent illness in such patients should be evaluated objectively, so as not to overlook any medical or surgical disease, which may strike a hysterical patient just as it does any other person.

The success of this program over a long period is not known. The eradication of some recently acquired hysterical symptom is relatively easy. The real test is whether it enables the patient to adjust satisfactorily to family and society and to perform daily activities effectively, and whether it prevents addiction, unnecessary medical treatments, and operations. Estimates of the recurrence rate of hysterical symptoms vary widely from 12 to 80 percent. In the series reported by Gitfeld and Guze and by Merskey, the recurrence of somatic symptoms of similar or of other types was as high as in sociopathies. We have seen a few patients with monosymptomatic hysteria (paraparesis, bizarre gait, crippling dystonia) that persisted for years on end regardless of treatment. The long-term poor prognosis for well-established symptoms in several series has been alluded to earlier. The use of a wheelchair for more than several days has been a bad prognostic sign in these cases.

Hypochondriasis

Hypochondriasis is the morbid preoccupation with bodily functions or physical signs and sensations, leading to the fear or belief of having serious disease. Hallmarks of this condition are the failure of repeated examinations to disclose any physical basis for the patient’s symptoms and the failure of reassurance to affect either the patient’s symptoms or his conviction of being sick. It is estimated that 85 percent of hypochondriasis is secondary to other mental disorders, chiefly depression, but also schizophrenia and the neuroses. In about 15 percent of cases, however, there appears to be no associated illness (primary hypochondriasis). Most patients in this latter category are habitues of medical outpatient clinics, who are passed from specialist to specialist, perplexing and angering doctors along the way, because their symptoms defy both satisfactory diagnosis and cure. Often referred to by house officers as “crock,” these patients seldom benefit from conventional therapy.

Related to hypochondriasis, but probably more delusional are young adults who present with a fixed somatic belief regarding a peculiar symptom such as that the tongue is swollen, the jaw is not properly aligned, or the penis is ulcerated, when in fact no such abnormalities are present. The malignant aspect of such an illness is the persistence of the symptom and disability that extends for years, all tests having been negative. Probably these patients should be treated like schizophrenic patients, which many of them probably are. What to do with patients who are less severely affected but have an unshakable belief that they have Lyme disease or environmental “allergies” depends on the context but the outcome can be almost as bad as for the worst hypochondriac patients.

The treatment of primary hypochondriasis is difficult if not impossible unless the physician keeps in mind the personality of the patient and the therapeutic goals. A psychodynamic outlook would suggest that for a variety of reasons, these patients need to retain their symptoms, so that the usual concept of “curing” is inapplicable. The presence of symptoms provides the context for a relationship with a physician. It is the continuation of this relationship, which is often the only dependable human contact in the patient’s life, and is the motivation for some hypochondriac patients. Such patients are best managed by general physicians who realize that these are patients who do not necessarily want or expect a cure, and who are content with small gains and the avoidance of unnecessary surgery.
THE SOCIOPATHIES

Antisocial Personality (Sociopathy)

Of all the abnormal personality types listed in Table 56-1, the antisocial is the best defined and the one most likely to cause trouble in the family and community. It has been defined (in DSM-III) as a state in which the individual “is always in trouble, profiting not from experience or punishment, unable to empathize with family or friends or to maintain loyalties to any person, group, or code. He is likely to be shallow, callous, and hedonistic, showing marked emotional immaturity with lack of sense of responsibility, lack of judgment, and an ability to rationalize his behavior so that it appears warranted, reasonable and justified.”

Since Prichard, in 1835, first described this condition under the term immoral insanity, there have been many attempts to give it a more precise definition and to avoid using it as a psychiatric wastebasket. At the turn of the century, Koch introduced the term psychopathic inferiority, implying that it was a constitutionally determined deviation in personality. Later the term psychopathic personality came into common use. Some authors used this last term indiscriminately to embrace all forms of deviant personality. Subsequently the term came to be used in a more restricted sense to define a subgroup of antisocial or aggressive psychopaths (antisocial personality disorder, DSM-IV). Aubrey Lewis has given a lucid account of the history of the concept of sociopathy. By far the best modern study of sociopathy is that of L. N. Robins, based on a 30-year follow-up study of 524 cases from a child guidance clinic and 100 controls. Other investigations of note are those of Cleckley, of McCord and McCord, and of Guze and coworkers, who studied psychiatric illness in large numbers of felons and their first-degree relatives. The descriptions that follow and the preceding quotation are taken largely from these writings and from those of Reid.

Clinical Description This condition, unlike the majority of psychiatric disorders, is manifest by the age of 12 to 15 years and frequently earlier. The manifestations of sociopathic behavior in children and adults are five to ten times more frequent in males than they are in females. It consists essentially of deviant behavior in which individuals seem driven to make trouble in everything they do. Codes imposed by family, school, religion, and society are broken. Seemingly, the sociopath acts on impulse, but after committing the unsocial act, he shows no remorse. The most frequent antisocial activities are theft, truancy, running away, associating with undesirable characters, indiscriminate sexual relations, repeated fighting, recklessness and impulsivity, lying without cause, vandalism, abuse of drugs and alcohol, and, later, inability to work steadily or keep a job. Fire setting and cruelty to animals have been added as common early features by several authors. In the study by Robins, of children or adolescents who exhibited 10

* Figures in parentheses represent the number of diagnoses of each personality disorder out of a total of 361 patients with the diagnosis of personality disorder at the Psychiatric Service of the University of Iowa (Winokur and Crowe).
or more antisocial symptoms, 43 percent were categorized as sociopaths in adulthood. If only 8 or 9 of these traits were present, 29 percent were so grouped; if 6 or 7, 25 percent; and 3 to 5, only 15 percent. Conversely, not a single adult sociopath was observed who did not manifest antisocial symptoms in earlier life. Interestingly, a number of other problems of childhood and adolescence—such as enuresis, dirty appearance, sleepwalking, irritability, nail biting, oversensitivity, poor eating habits, nervousness, being withdrawn or seclusive, unhappiness, tics, and fears—were not predictive of adult sociopathy. None of Robins’ patients was mentally retarded.

It should at the same time be noted that more than half the deviant children in Robins’ study (even those with 10 or more antisocial manifestations) had lost most of their sociopathic traits by adulthood. This does not mean that they remained psychiatrically normal. Of those who did not become adult sociopaths, the large majority developed other adult psychiatric illnesses, particularly addiction to alcohol. Only in the group of children with less than three antisocial symptoms did a reasonable number (one third) remain entirely well from a psychiatric point of view in adult life. Because sociopathic behavior in children may terminate spontaneously or evolve into other disorders, it is advised (in DSM-IV) that the diagnosis of antisocial personality disorder be reserved for adults; the same behavior pattern in children is designated as conduct disorder.

Also of interest are Robins’ findings that sociopaths showed an unusually high incidence of “conversion” symptoms (we would substitute “malingering,” see further on), as well as depressive symptoms and anxiety, and that the neurotic symptoms are in proportion to the sociopathic ones—i.e., the larger the number of antisocial manifestations, the larger the number of neurotic symptoms or the greater the disability from them. Among women with sociopathic behavior there was a high incidence of hysterical manifestations—evidence that female hysteria may be the counterpart of male sociopathy. In Robins’ series, a search for evidence of encephalitis, often postulated in the past as the basis of sociopathy, was not revealing, or was there any proof of other brain damage.

Electroencephalographic (EEG) abnormalities, taking the form of mild to moderate bilateral slowing, are more frequent in criminals and sociopaths than they are in the normal population but the meaning of this finding is unclear. Furthermore, the biologic parents of sociopaths also show a higher frequency of such EEG abnormalities than the general population. These and other findings suggest a genetic predisposition to antisocial personality. In a Danish study of criminals by Christiansen, “inappropriate nonpsychotic impulse-ridden behavior” was found five times more frequently in first-degree biologic relatives than it was in the general population. Criminality was two times more frequent in monozygotic twins than it was in dizygotic twins. His study confirmed an association between hysteria and sociopathy. More direct evidence of a genetic factor has been provided by Cadoret’s studies of adoptees who were separated at birth from antisocial biologic parents. A higher incidence of antisocial behavior was present in the adoptees than were in controls. This study also suggested that excessive childhood hyperactivity and classic female hysteria were phenotypic manifestations of an antisocial personality genotype.

There is no information as to the best methods of treatment and the role of the medical profession has never been clear. Most psychiatrists have been discouraged by the results of psychotherapy, but whether behavioral therapy, psychoanalysis, or drugs have more to offer cannot be determined from available data. Medical efforts should be directed to evaluating the patient’s neurologic status, assessing his intelligence, and explaining the nature of the disorder to parents and social agencies, tasks best performed by a psychiatrist.

**Malingering**

This problem arises frequently in connection with both hysteria and sociopathy and the physician should know how to deal with it. It is not a medical diagnosis except under the rare circumstances in which a patient is caught in the act of producing a sign of disease or confesses to having done so. The term malingering refers to the conscious and deliberate feigning of illness or disability in order to attain a desired goal. It does not appear as an isolated phenomenon, and its occurrence must be interpreted as a sign of a serious personality disturbance, often one that prevents effective work or military service, as a means of obtaining recompense for an alleged injury, although noteworthy exceptions to this statement can be found.

In the malingering one may observe pain, hyperesthesia, anesthesia, limping gait, tremor, contracture, paralysis, amaurosis, deafness, stuttering, mutism, amnesia, pseudoconvulsions and fugues, unexplained gastrointestinal bleeding, and unexplained skin lesions—in short, the same array of symptoms and signs, singly or in combination, as in the patients with compensation hysteria.

Certainly there is a similarity between hysteria and malingering, but the nature of the relationship is nebulous, and there may be great difficulty in establishing a clinical differentiation. As Jones and Llewellyn have observed:

> Nothing . . . resembles malingering more than hysteria; nothing, hysteria more than malingering. In both alike we are confronted with the same discrepancy between fact and statement, objective sign and subjective symptom—the outward aspect of health seemingly giving the lie to all the alleged functional disabilities. We may examine the hysterical person and the malingering, using the same tests, and get precisely the same results in one case as the other.

Most authors cite the following as the main points of difference between the two conditions: (1) The conscious or unconscious quality of the motivation, which seems more unconscious in the hysteria patient and more conscious in the malingering. (2) The influence of persuasion, which is usually effective in hysteria and not in the malingering. (3) The attitude of the patient. The hysteria patient appears more genuinely ill and invites examination; the malingering seems less ill and evades examination. The tendency of the sociopath to malingering has already been mentioned. Most of the more obvious cases of malingering seen by the present authors have been in sociopaths, for which reason discussions of the two conditions have been juxtaposed.

A particular form of sociopathy or malingering, which consists essentially of systematically and specifically deceiving the medical profession, has been described as Munchausen’s syndrome—named (not altogether aptly) after a seventeenth-century German soldier, Baron von Munchausen, who invented incredible tales of adventure and daring. Ireland and colleagues, who analyzed 59 well-documented cases (45 men, 14 women), list the following characteristic features, which will be recognized at once by all neurologists with extensive hospital experience: feigned severe illness of a dramatic and emergency nature; factitious evidence of disease, surreptitious interference with diagnostic procedures, or self-mu-
Intermittent Explosive Disorder

Designated by this title is an uncommon disorder, the characteristic feature of which is the occurrence of repetitive, unpredictable outbursts of violent, aggressive behavior out of all proportion to the provoking situation. This condition needs to be set apart from the uncontrollable outbursts of violent behavior that sometimes are associated with mental retardation, schizophrenia, drug addiction, or alcoholism, or those that follow serious head injuries or other brain diseases. Neurologic opinions have been solicited on our services by patients afflicted with this condition, the question often being raised as to whether such behavior may be the result of a brain lesion. The neurologic evaluations have been negative in the vast majority of cases. There have been some reports of impaired basal ganglia function in patients with this disorder, and neurosurgical consultation has been offered when deemed appropriate. Patients with the intermittent explosive disorder have, from early childhood, reacted to frustration with a loss of self-control, striking out in blind rage at anyone who crossed them (episodic dyscontrol syndrome); as adults, they may inflict serious injury or kill. Lesser degrees are recognized as expressions of “hot temper.” Sometimes such behavior appears to be a continuation of the temper tantrums of earlier childhood.

The causes of aggressive violence are poorly understood. There appears to be a heritable tendency (Cadoret et al); males predominate and a sex-linked form extending over several generations has been described. In only a very small number of patients, a seizure disorder can be identified, particularly temporal lobe epilepsy. Examples have been demonstrated in patients with temporal lobe tumors and encephalitis, raising the possibility that more cases have a pathologic basis but that the majority still appear to be constitutional in nature. Anergic hyperactivity has been suggested and supported to some extent by these patients’ response to propranolol (see Chap. 25 in the discussion on the limbic system). Most instances probably represent a variant of sociopathy. In DSM-IV, intense outbursts of anger and physical violence are also important features of a diagnostic category called borderline personality disorder, the other manifestations of which include “a pervasive pattern of instability of mood, interpersonal relationships, and self-image.” Elliott, and Jenkins and Maruta report a beneficial effect of propranolol. Others find lithium, carbamazepine, and phenytoin to be helpful in controlling and preventing the explosive attacks. We have noted the recent increased use by psychiatrists of serotoninergic antidepressants in these patients but have no way to judge their effect.

ANOREXIA NERVOSA AND BULIMIA

Anorexia nervosa is a behavioral disorder of previously healthy girls and young women living in affluent societies, mainly from upper and middle social classes, who become emaciated as a result of voluntary starvation. It is rare in Asian and African-American women and very uncommon in males. Herzog reminds us that it was Richard Morton who first described the condition in 1649, under the title of “nervous phthisis,” a “nervous consumption” resulting from “sadness and anxious cares”—a title that embodied enigmatic roots in psychologic derangements. Bulimia (literally ox-hunger), to which it is closely related, was not identified as an eating disorder until the latter part of the nineteenth century.

As a rule, anorexia nervosa begins shortly after puberty—sometimes later, but seldom after 30 years of age. Some of the patients have been overweight in childhood, especially in the prepubertal period. Dieting is much talked about and may have been encouraged, especially by mothers who want their daughters to become more attractive. In epochs such as the current one, where dieting and female thinness are popular, the illness seems to be more common and lesser forms of the disorder are rampant in high-school- and college-age young women. Sometimes there appears to be a precipitating event, such as leaving home, a disruption of family life, or other stress. Whatever the provocation, it leads to an obsessive refusal to eat. What is more important, the abnormal eating habits persist even when the patient has become painfully thin, and when counseled to eat normally, she will use every artifice to starve herself. Food is hidden instead of being eaten, vomiting may be provoked after a meal, or the bowel may be emptied by laxatives. No amount of persuasion will induce the patient to take adequate amounts of food. The patient shows no concern about her obvious emaciation and remains active. If left alone, these patients waste away, and about 5 percent have succumbed to some intercurrent infection or other medical complication, placing it among the most lethal of psychiatric conditions.

On physical examination, one is struck with the degree of emaciation; it exceeds that of most of the known wasting diseases. Often 30 percent or more of the body weight will have been lost by the time the patient’s family insists on medical consultation. A fine lanugo covers the face, body, and limbs. The skin is thin and dry, without its normal elasticity, and the nails are brittle. The dental enamel is eroded. Pubic hair and breast tissue (except for loss of fat) are normal, and in this respect anorexia nervosa is unlike hypopituitary cachexia (Simmonds disease). There are no neurologic signs of nutritional deficiency. The patient is alert and cheerfully indifferent to her condition. Any suggestion that she is unattractively thin or seriously depleted is rejected.

Amenorrhea is practically always present and may precede the extreme weight loss. Luteinizing hormone (LH) concentrations are reduced to pubertal or prepubertal levels. Clomiphene citrate fails to stimulate a rise in LH, as it does normally. Administration of gonadotropin releasing factor raises the LH and FSH levels, suggesting a hypothalamic disorder. The basal metabolic rate is low; T3 and T4 are low, while levels of physiologically inactive 3,3,5-triiodothyronine (reverse T3) are normal or increased. Plasma thyrotropin (TSH) and growth hormone levels are normal. Serum cortisol levels are usually normal; excretion of 17-hydroxysteroids is slightly reduced. In sum, there is evidence of hypothalamic-pituitary dysfunction; probably this is not primary but is secondary to starvation as indicated by the study of Scheithauer and colleagues who found no definite changes in the pituitary gland in 12 fatal cases. These abnormalities, most of which are probably secondary effects of weight loss, are summarized in the review by Becker and colleagues. Computed tomography scanning shows slight to mod-
The etiology of anorexia nervosa is unknown, although there is no lack of hypotheses. Holland and coworkers reported a strikingly high concordance in monozygotic twins as compared with dizygotic twins, indicating that constitutional factors are important. Earlier signs of hysterical tendencies, obsessional personality traits, and depression are mentioned as being frequent in some series but not in others. Certain polymorphisms in the serotonin transporter gene, of types different from those that have been tentatively attached to anxiety and to obsessive traits, have also been reported. These findings are difficult to interpret. A functional imaging study has shown activation of the left insula, amygdala, and cingulate and depression are mentioned as being frequent in some series but not in others. Certain polymorphisms in the serotonin transporter gene, of types different from those that have been tentatively attached to anxiety and to obsessive traits, have also been reported. The authors termed calorie fear rather than a specific biologic feature of the disease.

Reports concerning the percentage of first-degree relatives of anorectic patients with manic-depressive disease are also contradictory. An increased prevalence of neurosis or alcoholism has been noted in other members of the family. However, psychiatrists seem to agree that the patient does not have symptoms that conform to any of the major neuroses or psychoses. Certainly loss of appetite, lack of self-esteem and interest in personal appearance, and self-destructive behavior—common features of anorexia nervosa—are also symptoms of depressive illness, yet most of the patients do not look or admit to being dejected. Moreover, endogenous depression affects both sexes. The pathologic fear of becoming fat and the obsession with weight might be interpreted as a phobic or obsessionnal neurosis. A characteristic personality disorder has not been defined.

That anorexia nervosa is practically confined to females must figure in any acceptable explanation of the syndrome. Among psychiatric disorders, only hysteria has this sexual predilection. Yet most psychiatrists do not believe anorexia nervosa to be a manifestation of hysteria. Probably important is that anorexia nervosa has its onset in relation to the menarche, at a time when the female exhibits rather large fluctuations in appetite and weight. This suggests some imbalance in the satiety center, which has been related to the menarche. It is as though the appetite-satiety mechanism of the female hypothalamus were unstable.

The association of anorexia with structural disease involving the appetite centers has not been established, though the cases reported by Lewin and colleagues and of White and Hain are suggestive. Martin and Reichlin, in citing these rare cases, attribute the anorexia and cachexia to lesions of the lateral hypothalamus. A rare disorder of infants has been described under the title of ‘diencephalic syndrome.’ Progressive and ultimately fatal emaciation (‘failure to thrive’), despite normal food intake, in an otherwise alert and cheerful infant is the main clinical feature. The causative lesion has usually proved to be a low-grade astrocytoma of the anterior hypothalamus or optic nerve region (Burr et al). See Chap. 27 for further discussion and references.

Treatment The most effective treatment consists of winning the patient’s confidence, supportive psychotherapy, assignment of one individual to sit with the patient as each meal is eaten, and a gradual increase of a balanced diet (Anderson). Extreme cases require hospitalization. If the patient refuses to eat, tube feeding is the only alternative. As weight is gained over several weeks, the patient usually becomes more normal in her attitude toward eating and will continue to recover on this regimen at home. The menses will not return until considerable weight has been gained (about 10 percent above the weight at the time of the menarche). Our colleagues report better success with such a regimen when imipramine or fluoxetine is added. Others have found these drugs to be ineffective except in patients with prominent symptoms of depression.

Becker and colleagues emphasized the potentially devastating medical complications to which severely anorectic patients are prone and the need to evaluate and treat these problems at the same time that nutritional therapy is undertaken. In particular, an electrocardiogram is essential in order to exclude a prolonged QT interval—the presence of which contraindicates the use of tricyclic antidepressants and increases the risk of ventricular tachycardia.

On average, 50 percent of patients recover completely or almost completely (Steinhausen and Seidel). In the remainder, the outcome is quite unfavorable. They either relapse after an initial period of improvement or remain chronically anorectic. Many patients are said to lapse into a chronic nervous state characterized by a persistent preoccupation with food, weight, and dieting. It is generally appreciated that chronic anorexia nervosa significantly shortens life; after a mean follow-up period of 12 years, 11 percent of a group of 84 patients had died (Deter and Herzog), and 15 percent after 20 years (Ratnasuriya et al). Suicide is a major contributor to this high mortality rate (Sullivan).

The few adolescent boys that we have seen with this syndrome have recovered on antidepressant medication. A few cases due to tumors within the hypothalamus have been mentioned in Chap 27.

Bulimia This is a related eating disorder characterized by massive binge eating followed by the induction of vomiting or excessive use of laxatives. Insofar as the central psychologic disturbance is the pursuit of thinness at all costs, it is generally conceived as a variant of anorexia nervosa. Indeed, binge eating is a frequent manifestation of anorexia nervosa, although it also occurs as the only, or predominant, eating disorder. However, a close relationship with the menarche as well as emaciation and endocrinologic disturbances are not as evident in bulimic patients as in those with anorexia nervosa. Pope and colleagues reported considerable success in 19 of 20 bulimic patients treated with imipramine and followed for 2 years; the newer antidepressants appear to be equally effective. In general, the therapeutic benefit of these drugs is considerably greater in cases of bulimia than it is in anorexia nervosa.

CHAPTER 57

REACTIVE DEPRESSION, ENDOGENOUS DEPRESSION, AND MANIC-DEPRESSIVE DISEASE

Psychosis, in its broadest definition, refers to any major derangement in mental function in which the individual’s ability to perceive and interact with the environment is impaired. Hallucinations are a frequent accompaniment but do not alone define this category of illness.

From a neurologic perspective, there are four major categories of psychosis: (1) confusional-delirious states, (2) psychoses associated with focal or multifocal cerebral lesions, (3) affective disorders (manic-depressive and depressive psychoses), and (4) schizophrenia. The first two categories are discussed in Chaps. 20 and 22. The latter two groups are the subject of this and the following chapter.

Depression is perhaps the cause of more grief and misery than any other single disease to which humankind is subject. This view, expressed by Kline almost 40 years ago, is still shared by everyone in the field of mental health. The several forms of depression taken together are the most frequent of all psychiatric illnesses. In a tertiary general referral hospital, as indicated in the previous chapter, they accounted for an estimated 50 percent of psychiatric consultations and 12 percent of all admissions to one teaching hospital. Although depression has been known for over 2000 years (melancholia is described in the writings of Hippocrates), there is still uncertainty as to its medical status as a disease state (kraepelinian concept) or as a type of psychologic reaction (meyerian concept).

In other words, is it basically a biologic derangement or a response to psychosocial stress? An eclectic position is that both are correct—i.e., that there are two basic forms of depression: exogenous (an apparent cause) and endogenous (with no overt external cause) and that there may be an interplay between them.

In respect to endogenous depression and manic-depressive psychosis, genetic and neurochemical data cited further on support the kraepelinian view of a disease state. Nonetheless, a lay concept persists, perpetuated perhaps by some process-oriented psychiatrists, that events in one’s life, either distant or current, underlie all types of depressive illness. An unfortunate consequence of this view is the assumption that an inability to deal with these stresses represents a personal failure of sorts and may inhibit the acceptance of psychiatric help.

Of great consequence for clinical work, depressive states are often associated with obscure physical symptoms. For this reason they are more likely to come first to the attention of general physicians and internists than are other psychiatric entities. Moreover, the physical symptoms are frequently mistakenly attributed to anemia, low blood pressure, hypothyroidism, migraine, tension headaches, chronic pain syndrome, chronic infection, emotional problems, worry, and stress. Neurologists are most likely to encounter depressed patients who complain of fatigue and weakness, chronic headache, and difficulty in thinking or remembering. When depression masquerades as a chronic pain or a fatigue state or some other medical condition, it had been called masked depression or depressive equivalent.

Another important reason why all physicians should be knowledgeable about depressive illness in all its forms is the danger of suicide, which may be attempted and successfully accomplished before the depression is recognized. Timely diagnosis may prevent such a tragedy—one that is all the more regrettable since most depressive illnesses can be successfully treated.

Nosology and Classification

As remarked in Chap. 24, the term depression embraces more than a feeling of sadness and unhappiness. It stands for a complex of disturbed feelings (called mood, or affective, disorder)—which may include despair, hopelessness, sense of worthlessness, and thoughts of self-harm—associated with decreased energy and libido, loss of interest in personal affairs, impaired concentration, various abnormalities of behavior and appearance, and prominent physical complaints—the most important of which are insomnia, anorexia or overeating, headache, and various types of regional pain. At one extreme are depressive symptoms of psychotic proportions (including paranoid or somatic delusions), which create chaos in the lives of the patient and those close to him. At the other extreme are the common feelings of unhappiness, anhedonia (loss of pleasurable responses), discouragement, and resentment that occur in almost everyone as a reaction to the disappointments of everyday life, such as loss of employment, a failure to gain recognition, or unsuccessful sexual or social adjustment, all of which are closely linked in their duration to the persistence of the precipitant factors.

The place in this nosology of postpartum depression has not been clear as discussed in the next chapter. In severe cases it is sometimes difficult to differentiate this condition from postpartum psychosis, a more dramatic and well-defined disorder discussed in the next chapter. Many modern authors question the existence of a primary biologic depression that is tied to the postpartum period (see summary by Brockington). This is not in accord with general experience in which varying degrees of depression are quite common in the weeks after delivery and cannot simply be attributed to psychosocial factors or sleep deprivation.

An abnormally elevated mood, or mania, is about one third as frequent as depression. It may develop as a relatively pure, recurrent clinical state, or it may alternate or be intertwined with depression, in which case it has been referred to as manic-depressive disease (bipolar disorder in the classification of the Diagnostic and Statistical Manual of Mental Disorders, or DSM-IV). Hypomania and cyclothymic disorder are the names given to milder forms of mania and bipolar disorder, respectively. The DSM-IV classification also acknowledges the existence of mixed schizoaf-
fective states

Reactive Depressions and Depressions with Medical and Neurologic Diseases

Patients reacting to a medical or neurologic illness seldom express feelings of sadness or despair without mentioning physical complaints, such as easy fatigability, anxiety, tension headaches, dizziness, loss of appetite, reduced interest in life and love, trouble in falling asleep, or premature awakening. It follows that whenever these symptoms become manifest in the course of medical disease, they should arouse suspicion of a depressive reaction (Table 57-1).

Chronic pain is a particularly frequent somatic manifestation of depression. The pain may be based on an attendant disease but is prolonged, disabling, sometimes vague in nature, and recalcitrant to straightforward medical and surgical approaches. In other words, depressed mood exacerbates and prolongs pain of any type. All patients with chronic pain syndromes should be evaluated psychiatrically, as pointed out in Chap. 8.

In a number of major medical illnesses, depressive symptoms occur with such frequency as to become almost part of the disease. They constitute important diagnostic and therapeutic problems. Contrariwise, in certain chronic, occult diseases, symptoms such as lassitude and fatigue may resemble and be mistaken for a depressive reaction. Hypothyroidism, infectious mononucleosis, infectious hepatitis, carcinoma of the pancreas, lymphoma, myeloma, metastatic carcinoma, malnutrition, polymyalgia rheumatica, and frontal lobe tumors, especially meningoimias, may simulate depression for weeks or months before the diagnosis becomes evident. Sedative drugs, beta-adrenergic blocking agents, beta-interferon, and the phenothiazines may evoke a depressive reaction; corticosteroids can induce a peculiar psychiatric state in which confusion, insomnia, and either an elevation of mood or depression are combined. A depressed mood may also emerge during the tapering-off period of steroid medication or during their initial use (a hypomanic state is more common).

Of particular significance is the reactive depression that occurs on learning of a serious medical or neurologic disease. Often such an emotional reaction, which the physician may tend to ignore, is the dominant manifestation of a disease that threatens the life pattern and independence of the patient. Recognition by the patient that he has suffered a stroke or that she has cancer, multiple sclerosis, amyotrophic lateral sclerosis, or Parkinson disease is almost always followed by some degree of reactive depression, often with an element of anxiety. A prime example is the depression that follows myocardial infarction (Wishnie et al.). Usually it begins toward the end of the patient’s stay in the hospital and attracts little attention. Once the patient is home, fatigability that approaches exhaustion is the main complaint and interferes with accustomed activities. It may be described as weakness and falsely attributed to heart failure. Symptoms of irritability, anxiety, and despondency are next in order of frequency, followed by insomnia and feelings of aimlessness and boredom. Although most of these patients ultimately recover without medical assistance the depression exacts a high toll in terms of mental suffering.

An analogous depressive reaction occurs in some patients after a stroke. Some studies have indicated that patients with left anterior cerebral lesions, involving predominantly the lateral frontal cortex or basal ganglia (as detected by computed tomography scanning) and examined within several weeks of the stroke, have a greater frequency and severity of depression than do patients with lesions in other locations (Starkstein et al.; Robinson). According to these authors, lesions of the right hemisphere do not show this correlation with depression but do show a higher association with pathologic cheerfulness or mania. However, House et al., in a British community-based study of stroke survivors, failed to confirm these findings, perhaps because the infarcts were small in size (more than half the patients had never been admitted to hospital) and many patients were examined for the first time only at 6 and 12 months after their illness.
after their strokes. Our colleagues Levine and Finkelstein have reported the occurrence of psychotic depression with hallucinations and delusions in patients with right temporoparietal infarcts. Our own experience suggests a not surprising relationship between the degree of motor and language disability and the severity of post-stroke depression but a less predictable relationship to the location of the lesion. The possible predisposing effects of minor previous episodes of depression, family history of depressive illness, and medications have not been studied systematically.

With regard to emotional reactions in degenerative brain diseases, Parkinson disease is complicated by a depressive reaction in approximately one quarter of cases. Weakness and fatigability, the principal psychologic manifestations, are added to the bradykinesia, and the resulting therapeutic problem becomes formidable. Another hazard in Parkinson and in Lewy body disease is the tendency for L-dopa itself to provoke a depression in a limited number of patients, sometimes with suicidal tendencies, paranoid ideation, and psychotic episodes. Huntington chorea is quite often associated with depression, even before the movement disorder and dementia become conspicuous. In one series, 10 of 101 patients with Huntington disease either committed suicide or attempted it. Also, Alzheimer disease may be accompanied by depressive symptoms, in which instance it is difficult or impossible early in the illness to evaluate the relative contributions of the mood disorder and the dementia. In later stages, the overt signs of depression abate.

ENDOGENOUS DEPRESSION AND MANIC-DEPRESSIVE DISEASE

Definitions and Epidemiology

Manic-depressive disease is a disorder of mood consisting of prolonged episodes of depression, mania, or both. It was given its name by Kraepelin in 1896, and it was with him that our current clinical concept of this disorder originated. He viewed the manic and depressive attacks as opposite poles of the same underlying process and pointed out that, unlike dementia praecox (his name for schizophrenia), manic-depressive psychosis entails no intellectual deterioration with recurrent episodes. A traditional view of this disease was that of a periodic or cyclic condition in which one major mood swing was followed by an equal but opposite excursion. This is seldom the case, however. Episodes of depression are more than twice as frequent as manic ones, and according to current thinking, the most common form of the illness is characterized by episodic depression alone. Recurrence of episodes of pure mania without interspersed episodes of depression is well known but relatively uncommon. As a consequence, manic-depressive psychosis has been divided into two subtypes: the unipolar group, in which only an endogenous depressive illness occurs, and a bipolar group, in which one or more bouts of mania occur with or without depression. The bipolar variety occurs in about 10 percent of patients with affective disorder. The biologic accuracy of this classification has not been critically determined.

In addition, there are mixed affective states, in which symptoms of both depression and mania occur within a single episode of the illness. A so-called “rapid-cycling” form of manic-depressive disease has been recognized in which four or more circumscribed episodes occur in a year. Like other variants of the disease, it tends to have an aberrant or unpredictable response to medication. Still other patients with affective elements of depression present with atypical features; instead of anorexia, weight loss, and insomnia, for example, they sleep and eat excessively. These patients are also less responsive to therapy. In adolescents, the latter symptoms are difficult to differentiate from the Kleine-Levin syndrome (page 344).

The prevalence of manic-depressive disease cannot be stated with precision, mainly because of varying criteria used for diagnosis. The apparent increase of the disease in the past 50 years probably reflects a growing awareness of the condition among both physicians and the laity. Studies of large groups of patients from isolated areas of Iceland and the Danish islands of Bornholm and Samsø have indicated that 5 percent of men and 9 percent of women will develop symptoms of major depression, mania, or both at some time during their lives (Goodwin and Guze). The estimate for an American urban community in 1978 (New Haven, Connecticut) was higher; 8 to 12 percent in men and twice this number in women (Weissman and Myers).

Manic-depressive disease occurs most frequently in middle and later adult years, with a peak age of onset between 55 and 65 for both sexes. However, a significant proportion of patients experience the first attack in childhood, adolescence, or early adult life. Depression is also a significant problem in the elderly. Blazer and Williams, who studied 997 persons over the age of 65 in North Carolina, found symptoms of a major depressive illness in 3.7 percent. The disease was two or three times more frequent among women. There is no known explanation for this gender difference, but some have speculated that just as many men are depressed, only they deny it or turn to alcohol. Patients in the bipolar group have an earlier age of onset, more frequent and shorter cycles of illness, and a greater prevalence of affective disorder among their relatives than do patients with unipolar depression (Winokur).

Clinical Presentation

Fully developed endogenous depression may evolve within a few days, or, more often, it emerges more gradually, on a background of vague prodromal symptoms that had been present for months. A detailed description of the symptoms and signs of depression is given in Chap. 24. Here it need only be repeated that the patient expresses feelings of sadness, unhappiness, discouragement, hopelessness, and despondency, with loss of self-esteem. Reduced energy and activity, typically expressed as mental and physical exhaustion, is almost always present, to the point of catatonia in the most severe cases. Indeed, the most common cause of symptoms relating to reduced psychic and physical energy and drive (connation) is depression. There is heightened irritability as well as a lack of interest in most activities that formerly were pleasurable. The patient tends to move slowly, sighing is frequent, and speech is reduced. The mental life of such an individual may narrow to a single-minded concern about physical or mental decline or both. In dialogue, the patient’s responses become so stereotyped that the listener can soon predict exactly what is going to be said. There is a poverty of ideation and sometimes a notable absence of insight. Consciousness is clear, and though there is no evidence of a schizophrenic type of thought disorder, delusional ideas and less often hallucinations may be prominent in some patients, justifying the term depressive psychosis. The delusions are generally congruent with the patient’s mood and are not as fixed or bizarre as those of schizophrenia or paranoia. In our experience, delusions are more common in older patients and tend to appear only after weeks or months of more typical symptoms of depression. Hallucinations, when they occur, are usually transitory, vocal, and vaguely accu-
satory; their presence should always raise the possibility of an associated structural brain disease, drug intoxication, or alcoholic auditory hallucinosis.

Frequently, agitation and irritability rather than physical inactivity and mental slowness are the principal behavioral abnormalities. The source of the agitation is an underlying anxiety state. Pacing the floor and wringing the hands, particularly in the early morning hours, are characteristic. Such patients tend to be overly talkative and vexed in their manner of expression, irritable, short-tempered, impatient, and intolerant of minor problems—changes noted mainly by family members. Attempts at reassurance may meet with initial success, only to be dispelled in the next rush of doubts. These patients remain impervious to reason and logic with respect to their symptoms, even though they are reasonable and logical to a variable degree in other areas of their lives. At its worst the illness takes the form of a depressive stupor; the patient becomes mute, indifferent to nutritional needs, and neglectful even of bowel and bladder functions (anergic depression). The condition in this extreme form is a catatonic depression. Such patients must be fed and their other needs attended to until therapy [usually electroconvulsive therapy (ECT)] brings about improvement.

The most important concern in patients with mid- and late-life depression is the risk of suicide. Since many of these individuals have reputations for being sound, dependable, and stable and deny being depressed, one’s inclination is to doubt the possibility of self-destruction. Such patients should be questioned forthrightly on this subject: Do they feel that life is not worthwhile? Have there been thoughts of suicide? Do they think themselves capable of committing suicide? Have they made such plans or made suicide attempts before? Is there a family history of suicide? Do they own a firearm? Are they fearful of dying? Are they concerned about leaving their family without support? Do they have a strongly held religious view that proscribes suicide? These questions relate to features that have been shown to put depressed individuals at risk of suicide. If, from their answers, they are judged to carry an imminent risk of suicide, they should be directed to a psychiatrist and generally admitted to a hospital.

In some depressions, hypochondriacal preoccupation with bowel and digestive functions accounts for repeated visits to the medical clinic. In one study, 21 of 120 such patients were subsequently diagnosed as being depressed. Persistent insomnia may be the major complaint of the depressed patient. Early awakening is typical, and the morning hours are then the worst period of the day. Other patients have difficulty falling asleep, especially if there is an associated anxiety state. A complaint in the male of loss of libido and impotence is another monosymptomatic presentation; only with probing inquiry about other disturbances common to depression will the diagnosis become evident.

The manic state is, in most ways, the opposite of the depressed state, being characterized by a flight of ideas, motor and speech hyperactivity, and an increased appetite and sex urge. When such a state is fully developed, it qualifies as a psychosis. After a minimum of sleep, the patient awakes with enthusiasm and expectation. The manic individual appears to possess great drive and confidence yet lacks the ability to carry out plans. Headstrong, impulsive, socially intrusive behavior is characteristic. Judgment may be so impaired that reckless investments are made; fortunes are spent in gambling or on extravagant shopping sprees. Setbacks do not perturb the patient, but rather act as goads to new activities. Euphoria and expansiveness sometimes bubble over into delusions of power and grandeur, which, in turn, may make the patient offensively aggressive. Up to a point, the patient’s mirth and good spirits may be contagious, and others may join in; however, if the patient is thwarted, the warmth and good humor can suddenly change to anger. Irritability rather than elation may become the prevailing mood. The threshold for paranoid thinking is low, which makes the patient sensitive and suspicious. Personal neglect may reach the point of dishevelment and poor hygiene. In its most advanced form, a condition described as “delirious mania,” the patient becomes totally incoherent and altogether disorganized in behavior. At this stage visual and auditory hallucinations and paranoid delusions may be rampant; furthermore, as the term delirium implies, the patient may be disoriented and agitated, with a clouded sensorium. This extreme is rarely encountered. As mentioned earlier, one observes patients with repeated attacks of mania without depression at any time, but this is not common.

Hypomania represents a milder degree of the disorder, but this term is also used loosely to depict behavior in a normally functioning individual who is unusually energetic and active. In this latter sense hypomania is a personality trait found in many talented and productive persons and need not arouse concern unless it is excessive and out of character for the individual. This is best determined by questioning the family. As commented in the review by Belsmaker, a number of highly creative individuals have had bipolar disorders, but full-blown mania is uniformly destructive of careers and personal relationships. He cites Shou in pointing out that such individuals are actually more creative when treated with appropriate medications.

First attacks of either depression or mania last an average of 6 months if untreated, although the duration varies greatly. With treatment, this can be reduced by more than half in most patients. Although most attacks of manic-depressive disease subside in a matter of months, a significant number, unipolar patients more than bipolar ones, remain chronically ill for long periods. According to Winokur and colleagues, 14 percent of their bipolar patients had not recovered after 2 years and 5 percent after 5 years. Comparative figures for primary unipolar patients were 19 and 12 percent, respectively. Well over one half of all depressed patients have one or more recurrences. Variables that are predictive of an unfavorable outcome are high degrees of neuroticism, strongly positive family history of a similar psychiatric illness, and presence of depression-provoking circumstances (Hirschfeld et al). Perhaps most important is the duration of illness before treatment, i.e., earlier treatment is generally associated with a more favorable prognosis.

Diagnosis

According to DSM-IV, the essential diagnostic criteria of endogenous depression (“major depressive syndrome”) consist of a dysphoric mood or loss of interest or pleasure in all usual activities (including sexual activity) in combination with at least four of the following seven symptoms: (1) disturbance of appetite and change in weight; (2) sleep disorder; (3) psychomotor retardation or agitation; (4) decreased energy and fatigue; (5) self-reproach, feelings of worthlessness or guilt; (6) indecisiveness, complaints of memory loss and difficulty in concentrating; and (7) thoughts of death or suicide or actual suicide attempts. In this diagnostic scheme, each of the four diagnostic symptoms should have been present for at least 2 weeks.

Adherence to the aforementioned criteria undoubtedly facilitates diagnosis, but not infrequently a single one of these symptoms so dominates the clinical picture as to suggest the diagnosis of
another disease state and obscure the presence of an underlying depression. As mentioned earlier, depressed patients who are referred to the neurologist tend to complain inordinately of physical and cognitive symptoms and to minimize or deny the purely affective ones. Complaints of fatigue, weakness, malaise, or widespread aches and pains, for example, suggest a variety of medical diseases, such as Addison disease, hypothyroidism, chronic infection, polymyositis, or early rheumatoid arthritis. Often the fatigue state is misinterpreted as muscular weakness, and this directs a medical search for neuromuscular disease. Similarly, complaints of persistent headache may suggest the presence of intracranial disease. Complaints of poor memory, inability to concentrate, and other cognitive impairments raise the question of a dementia—until it is found, by careful examination, that mental competence belies the patient’s appraisal of his own presumed defects.

A number of psychologic testing scales are used to detect and score the severity of depression. Although they are of value mainly for clinical studies, several of them can be quite helpful in clinical works, since they are sensitive to one or another aspect of depression. They do not supplant the clinical examination in determining if an individual is depressed or suicidal but they may be helpful in differentiating depression from dementia and in detecting depression in cases where physical complaints are more prominent than psychic ones. The tests most familiar to neurologists are the Hamilton and the Beck scales, but several others are as valid.

In our experience, the following are some of the common and troublesome clinical situations in which it may prove difficult to recognize an underlying depression:

1. Patients with chronic pain. The association of chronic pain and depression has long been appreciated. This is far from a homogeneous group. The special case of chronic headache, confronted often by neurologists, is discussed later. In some patients with chronic pain, the symptoms and signs of depression are quite apparent. If the pain has been present for less than a year and had its onset at the same time as other depressive symptoms, response to antidepressant treatment is likely to be favorable.

Far more difficult to understand, and to manage, are patients with persistent pain as the only complaint; the head, face, and lower back are the most common loci. Among the depressive pain syndromes, intractable headaches may be the most prominent manifestation of depression seen by neurologists. Weeks or months of unremitting daily tension-type headaches in the context of a normal examination are highly suggestive of depression at any age. If an exhaustive search for the source of the pain proves unsuccessful, the conclusion is finally reached that the pain is “psychogenic.” This attribution of pain to some obscure psychologic mechanism is hardly helpful, for usually no amount of exploration will reveal its source. Nevertheless, in a small proportion of such patients, pain will be alleviated by antidepressant drugs, suggestive, at least in these cases, of a linkage of the pain and depression. In this group of patients, the problem is frequently made even more difficult by repeated surgical operations as well as dependency on analgesic drugs, which in themselves deplete energy and have other adverse effects. Such patients are to be found among those disabled after multiple operations for prolapsed intervertebral disc or arthritic hips or those with atypical facial pain.

2. Depression and alcoholism. These are commonly associated, and it is important to determine which is primary and which is secondary. A depressive syndrome developing for the first time on a background of alcoholism is a common clinical occurrence. In a large series of alcoholic patients studied by Cadoret and Winokur, a secondary depression occurred in 30 of 61 females and in 41 of 112 males; moreover, once the alcoholism was established, depression became evident much earlier in the women than in the men. The opposite occurrence (i.e., the development of alcoholism on the background of a primary depression) is less common. Again, women are disproportionately affected. As mentioned earlier, these differences may be spurious; Winokur’s family studies have suggested that the same genetic predisposition leads to depression in females and alcoholism and sociopathy in men.

3. Depression in childhood and adolescence. We have observed depressive states in children, and they have often been misdiagnosed by both pediatricians and psychiatrists. The common manifestations have been chronic headache, refusal to go to school, withdrawal from social activities, anorexia, vomiting and weight loss, and scholastic failure. Puberty is a time of onset in many cases, but we have seen depressive disease in late childhood, and it is extremely frequent in high school and college students. It is a tragic mistake not to appreciate this fact and to treat the patient for some presumed nonaffective nervous symptoms, only to have the patient commit suicide. This has happened to more than half a dozen of the children of our medical colleagues over the years.

4. Anxiety neurosis, hypochondriasis, and pseudodementia. These are clinical circumstances in which an underlying depressive illness may not be immediately apparent but must always be suspected. These symptoms are discussed in detail in the preceding chapter. The complaint of severe chronic fatigue without medical explanation should raise the same suspicion (Chap. 24). An elderly person with seemingly early signs of dementia may, on closer examination, turn out to have a severe depressive illness (pseudodementia, page 375).

Etiology of Depression

The following are the main theories, not mutually exclusive, that have been proposed to explain the origin of depression; for a detailed review of the subject, the reader is referred to Nestler.

Genetic Factors The capacity to experience sadness and depression is common to all people but there is no question that some individuals are more liable to depression than others who are subjected to similar psychosocial forces. It has been estimated, using various genetic techniques, that as much as 40 to 50 percent of the risk of depression is heritable. Adopted children whose biologic parents had affective disorder are at greater risk of developing this disease than adoptees whose biologic parents were not affected (Mendlewicz and Rainer; Cadoret). The frequency of these illnesses is greatly increased in the relatives of affected patients (prevalence rate of 14 to 25 percent in first-degree relatives). Similarly, the risk of depression among first-degree relatives is increased (15 percent, in comparison to 1 to 2 percent risk in the general population). If several twin studies are taken together, 72 percent of monozygotic twins are concordant for bipolar disease, compared with 14 percent of same-sex dizygotic twins; comparative figures for unipolar disease are 40 percent and 11 percent, respectively.
ever, most of the neurochemical theories of depression suffer from the weakness that they have been the result of a type of backward reasoning from the biochemical effects of antidepressants on various neurotransmitters to the putative mechanisms of the disease. Following the observations that the tricyclic antidepressants and the monoamine oxidase (MAO) inhibitors exerted their effect by increasing norepinephrine and serotonin at central adrenergic receptor sites in the limbic system and hypothalamus, and that depression-provoking drugs (such as reserpine) deplete biogenic amines at these sites, it was proposed that naturally occurring depressions might be associated with a deficiency of these substances. Furthermore, depressed patients and their first-degree relatives, as well as healthy individuals, develop a depressed mood after dietary depletion of the monoamine precursor tryptophan. Also noteworthy is the reduced concentrations of 3-methoxy-4-hydroxyphenylglycol (MHPG), a metabolite of norepinephrine, in the cerebrospinal fluid (CSF) of patients during endogenous depression and the elevated levels in manic states. Some neurochemical imaging studies corroborate these findings and others do not. Along similar lines, 5-hydroxyindoleacetic acid (5-HIAA), a deaminated metabolite of serotonin, is reduced in the CSF of depressed patients (Carroll et al).

Certain of the newer antidepressants act as selective serotonin reuptake inhibitors (SSRIs) and apparently produce their salutary effects by increasing the amount of serotonin that is functionally active in the synapse (they also raise the concentrations of norepinephrine). For these reasons, serotonin and its neuronal pathways are also currently implicated in the genesis of depression. However, the reader should be reminded that only a decade ago it was widely held that depletion of norepinephrine fulfilled this role. It is also not yet clear which neurochemical alterations are primary and which modulate other systems. For example, reports suggest that substance P plays an important role in the causation of depression (Kramer et al) and that blockade of substance P receptors has antidepressant effects. Why there is a delay of several weeks in the improvement of depression related to the taking of the various antidepressants is unexplained by any of the neurochemical models.

Another set of observations that has continued to capture interest for more than a decade, implicates a disorder of hypothalamic-pituitary-adrenal function as another component of depression (summarized by Schlesser et al.). It had been found several decades ago that the parenteral administration of 1 to 2 mg of dexamethasone failed to suppress serum cortisol secretion while the patient was ill with endogenous depression but did so after recovery. In a comparable series of reactive depressions, there was a normal suppression of cortisol secretion. Originally the dexamethasone suppression test was believed to separate the two large groups of depressed patients and to predict the response to drug therapy. However, subsequent studies have shown that the specificity of this test was less than earlier reports had indicated (Amsterdam et al, Insel et al). Nonetheless, accumulated evidence now indicates that one half of severely depressed patients do not show suppression of cortisol secretion, and a positive test can be obtained in a significant number of patients with other psychiatric disorders.

The failure of dexamethasone suppression has been attributed to hyperactivity in the hypothalamic pituitary axis and a corresponding increase in secretion of corticotropin-releasing hormone, ACTH and glucocorticoids. Elevated levels of glucocorticoids have been theorized to impede neurogenesis in the medial temporal lobe and perhaps to explain or exaggerate the loss of hippocampal neurons demonstrated in some studies of the brains of deceased depressed patients. A proposal that ECT acts by elevating levels of...
neurotrophic factors is at least consistent with this view and with the hypothesis that one component of recovery from depression is in some way associated with restoration of normal neuronal architecture in regions of the hippocampus and the hypothalamus (Chen). Although highly speculative, perhaps some of these changes explain the delay in improvement after the administration of antidepressant drugs.

At the present time, it must also be conceded that there is no reliable biologic test for depression. One must resort to clinical analysis (i.e., the interpretation of symptoms and signs) not only for diagnosis but also for the differentiation of special types of depressive reactions.

**Psychosocial Theories** Many experienced psychiatrists have emphasized the importance of psychosocial factors in the genesis of depressive illness. Among patients with primary depressive disorders, life events of a stressful nature were found to have occurred more frequently in the months preceding the onset of depression than in matched control groups. In the study by Thomson and Hendrie, this was equally true of patients with a positive family history of depression and those without such a history. Nor did patients with endogenous depression differ in this respect from those with reactive depression. Left unanswered is the question of why some individuals are subject to a reactive depression. Are they predisposed by psychologic or personality makeup? Perhaps the genetically transmitted factor is a heightened vulnerability to the effects of psychosocial stress. Epidemiologic data favoring one or another of these speculations are lacking. One is tempted to conclude that many depressions attributed to psychosocial stress are contaminating a group of endogenous depressions. Psychiatrists have also failed to find a consistent correlation between depressive illness and personality type or a particular psychodynamic mechanism. In our view, the adoption studies noted tend to diminish the importance of environmental factors in explaining most major depressions.

**Treatment**

The use of medications for depression is now so widespread that all physicians should be familiar with them. The physician untrained in psychiatry would, however, be unwise to undertake the management of manic-depressive disease or endogenous depression without the advice or assistance of a psychiatrist. If the symptoms are primarily neurologic (e.g., chronic headache, generalized weakness and fatigueability) and if there is a low risk of suicide, it is appropriate for the experienced neurologist or generalist to institute treatment with antidepressant medication. If there is any suspicion of suicide, the patient should be hospitalized and, if necessary, involuntarily committed.

**Antidepressant Medication** In the management of bipolar and unipolar disease, five main categories of drugs are in general use—the tricyclic antidepressants, the “atypical” or nontricyclic group of compounds, the MAO inhibitors, serotonin agonists (reuptake inhibitors), and lithium. The pharmacologic properties and modes of action of these drugs have already been considered in Chap. 43 (pages 1026 to 1028). Additional points of therapeutic interest are mentioned here. It should also be stated that meta-analyses of several large studies on the therapeutic effects of antidepressants have suggested that clinical improvement attributable to the drugs themselves occurs in only about one half of patients; remarkably, an additional improvement in up to 25 percent has been attributable to a placebo effect or to the natural course of the disease. The remainder fail to improve in a timely manner or relapse while on medication.

Most psychiatrists currently prefer to begin treatment with one of the functional serotonin agonists (SSRIs)—fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), citalopram (Celexa), and others, or one of a related group, exemplified by venlafaxine (Effexor) and nefazodone (Serzone). New ones of similar type are appearing yearly. These drugs have less sedating and anticholinergic effects than the tricyclic antidepressants discussed earlier. Fluoxetine has a tendency to produce insomnia and weight loss, making it particularly useful in the treatment of depressions that are characterized by overeating and hypersomnia. Some female patients have experienced an opposite effect, i.e., weight gain. Patients with anorexia, insomnia, and high levels of anxiety may do better with a more sedating medication, such as amitriptyline. In a similar vein, fluoxetine would be a reasonable choice for patients in whom lethargy is a prominent complaint. Certain side effects such as loss of libido or impotence occur in a proportion of patients and are difficult to differentiate from the signs of depression.

The tricyclic antidepressants comprise amitriptyline (Elavil), imipramine (Tofranil), doxepin (Sinequan), clomipramine (Anafranil), and trimipramine (Surmontil), and the closely related drugs desipramine (Norpramin), nortriptyline (Pamelor), and protriptyline (Vivactil). Among this group, most psychiatrists start with imipramine or amitriptyline because of their relative safety. In general, all of these drugs are equally effective, although an individual patient may have a better response to one than to another. The starting dose for amitriptyline or imipramine is 25 mg/day, which is then raised by 25 mg every 3 to 4 days as needed up to 150 mg/day. These drugs, taken at bedtime, are also very helpful in alleviating the insomnia that accompanies depression. The therapeutic effect of tricyclic medication is generally not evident for 2 to 4 weeks after treatment has been initiated, and it is important that this be explained to the patient and family. Common side effects are orthostatic hypotension, dry mouth, constipation, tachycardia, urinary hesitancy or retention (especially in patients with prostatic hypertrophy), tremor, and drowsiness. Closed-angle glaucoma may decompensate. Caution should be exercised in elderly patients with cardiac disorders of all types. For such patients, the serotonin drugs or one of a newer group of nontricyclic antidepressant drugs—bupropion (Wellbutrin) and trazodone (Desyrel)—may be preferable. The latter drugs appear to be as effective as the tricyclic agents in the treatment of depression without the adverse anticholinergic and cardiotoxic effects.

If one of the aforementioned drugs, given in full doses for 4 to 6 weeks, does not produce the desired effect (or if the patient is intolerant of the given drug), another one from an alternative group, e.g., an MAO inhibitor, may be tried. In the case of SSRIs, **there must be a drug-free interval of 1 to 2 weeks before instituting an MAO inhibitor**. Some studies suggest that MAO inhibitors are superior in depression with atypical features such as increased appetite. Phenelzine (Nardil), isocarboxazid (Marplan), and tranylcypromine (Parnate) are in this category, of which the first is said to be the least likely to produce serious side effects. The usual starting dose is 15 mg tid, which is gradually increased as needed to a maximum of 45 mg tid. The most serious risk of MAO inhibitors is the occurrence of a hypertensive crisis; therefore, these drugs should be dispensed with caution in patients with hypertension and with cardiovascular or cerebrovascular disease. Patients...
taking these drugs should avoid foods with a high tyramine content (aged cheese, pickled herring, chicken liver, beer, wines, yeast extract) as well as medications containing sympathomimetic agents or L-dopa (decongestants, amphetamines, caffeine) and the aforementioned serotonin agonists.

Supplementation of antidepressants with the administration of an anticonvulsant is a popular approach with many psychiatrists. Valproate or gabapentin are used, but also carbamazepine or phe- nytoin. There are few credible studies by which to judge the value of this strategy, but these drugs may provide some additional benefit as “mood stabilizers,” if only as antiaggressiveness agents. More persua- sive are the data suggesting that anticonvulsant drugs are useful in treatment of the manic state.

Since many patients are responsive to one of the tricyclic drugs, MAO inhibitors, or serotonin agonists but not to all of them, the clinician is greatly aided by information regarding which of these drugs has been most helpful in the past. This will guide one in current management. As mentioned, response to antidepressant drugs is not expected for several weeks. Treatment should then be continued for 4 to 6 months and generally should be combined with some type of psychotherapy. The dosage of medication should then be reduced slowly over a period of weeks. Rapid reduction may result in withdrawal symptoms (nausea, vomiting, malaise, and muscular pains). If depressive symptoms recur upon withdrawal, the effective dose should be gradually reinsti-tuted.

Lithium Carbonate This is the drug of choice in treating the manic phase of manic-depressive disease and it is useful in prevent- ing relapses of depression in some patients. Hospitalization is usually required to protect the manic patient from impulsive and aggressive behavior which might cause a loss of standing in the community or jeopardize a career. Chlorpromazine (Thorazine), haloperidol (Haldol), or one of the newer antipsychotics dis- cussed in the next chapter—or ECT if these drugs are ineffective—can be used to control the mania until lithium carbonate becomes effective, usually a matter of 4 or 5 days. The usual dosage of lithium is 1200 to 2400 mg daily in divided oral doses, which produces a desired serum level of 0.9 to 1.4 meq/L. The serum level of lithium must be checked frequently, both to ensure that a therapeutic dose is being taken and to guard against toxicity (see later).

The side effects of lithium are nausea and vomiting, diarrhea (especially if the dose is increased too rapidly), a feeling of mental dullness, action tremor, weakness, ataxia, slurred speech, blurred vision, dizziness, nystagmus (especially vertical or down beating), stupor, and coma. A confusional psychosis with polymyoclonus and ataxia simulating Creutzfeldt-Jakob disease (including periodic sharp waves in the electroencephalogram) may occur at toxic lev- els. In patients who do not tolerate lithium, carbamazepine or val- proate may be substituted. A combination of lithium and a tricyclic or SSRI medication at the lowest effective level has been one of the best long-term preventive therapies for manic-depressive dis- ease, and the same combination is useful for patients with mixed bipolar disorder in which depressive and manic manifestations oc- cur within a single episode of illness.

Electroconvulsive Therapy (ECT) and Transcranial Magnetic Stimulation ECT continues to be a highly effective treatment for severe endogenous depression and can also be used to interrupt manic episodes. The latter often requires only two or three treat- ments. The technique is relatively simple and safe. The patient is anesthetized by an intravenous injection of a short-acting barbitu- rate, benzodiazepine, or propofol and also medicated with a muscle relaxant (succinylcholine). An electrode is placed over each temple and an alternating current of about 400 mA and 70 to 120 V is passed between them for 0.1 to 0.5 s. The succinylcholine prevents strong and injurious muscle spasms. The patient is awake within 5 to 10 min and is up and about in 30 min. The mechanism by which ECT produces its effects is not known. Treatments are usually given every other day for 6 to 14 sessions. The only absolute contraindi- cation is the presence of increased intracranial pressure, as may occur with a neoplasm or hematoma. Whether epilepsy is precipitated or worsened by ECT is still debated. This treatment should also be used cautiously in the presence of uncontrolled systemic hypertension or with a known sensitivity to the anesthetic agents that are used as premedication (malignant hyperthermia; page 1272).

The major drawback of ECT is the production of a transient impairment of recent memory for the period of treatment and the days that follow, the degree of impairment related to the number of treatments given. Placing both electrodes on the nondominant side (unilateral ECT) or using lower amounts of current and a pulse rate rather than a sine wave may produce less memory disturbance but has been somewhat less effective against the depression. With the recognition that transcranial magnetic motor stimulation sometimes produced an elevation of mood, its use as a substitute for ECT has been suggested. The magnetic technique has the advantage of being free of any but minor physical effects, and since it produces no loss of consciousness, anesthesia and neuro- muscular paralysis are not needed. Brief pulses of high-frequency stimuli are used. Few controlled studies have as yet been per- formed, but the initial results have been promising, and this tech- nique could conceivably replace ECT. Whether it is as effective for severe depressions and catatonia is not yet known.

Until the advent of the antidepressant drugs, ECT was the treatment of choice for the agitated depression of middle and late life and for catatonia. Following a course of 6 to 14 treatments, close to 90 percent of patients recover within 2 months or less. Prior to the use of ECT, this type of depression might last for 2 years or longer before remission occurred. In cases of catatonia or severe psychotic depression most psychiatrists favor the initial use of a neuroleptic agent, such as haloperidol, followed by a trial of an antidepressant, before resorting to ECT. Following ECT ther- apy, maintenance therapy with a tricyclic compound, serotonin ag- onist, or lithium is necessary to prevent relapse.

Psychotherapy In all patients with manic-depressive disease, frequently repeated explanations of the patient’s illness, reassur- ance that the illness is self-limited, and encouragement and instruc- tion of the family are of value in helping the patient and family to understand the illness and cope with it. As a general rule, manic- depressive illness is best managed by a physician who is willing to follow the patient over a long period of time and who is known to the family. He should be available to reevaluate the patient on suspicion of a relapse. Although the prognosis for any individual attack is relatively good, it is wise to arrange for a plan of action that will be set in operation at the first hint of a recurrence.

Tomes have been written about various psychodynamic ap- proaches to psychotherapy and the authors are unable to comment reliably on them. A structured and problem-oriented approach to psychotherapy, utilizing “cognitive-behavioral” and “interper- sonal” strategies, has gained considerable popularity since its in- troduction in the 1970s by Beck. It draws to a limited extent on
psychoanalytic and other psychodynamic theories and has been used in patients with depression and in those with neuroses, chronic pain, sexual dysfunction, and other disorders. According to Blenkiron, cognitive-behavioral therapy is most effective in patients with mild to moderate (not chronic) depression, generalized anxiety and panic disorder, and obsessive-compulsive and phobic disorders. Essentially, in the short term, the therapist provides the patient with information on the nature of the illness, its common symptoms, and the active interventions that are to be undertaken to alter the specific misperceptions and the dysfunctional behaviors that spring from them. The interested reader can find discussion of this subject in the current edition of Kaplan and Sadock’s Comprehensive Textbook of Psychiatry (Sadock and Sadock, eds.). Noteworthy is the opinion of Gabbard that behavioral-cognitive psychotherapy has been shown to be no better or worse than other forms of psychotherapy.

Suicide

Some 30,000 suicides are recorded annually in the United States, and attempted suicides exceed this number by about 10 times. All psychiatrists agree that these are conservative figures. Suicide is the eighth leading cause of death among adults in the United States and the second leading cause among persons between the ages of 15 and 24 years, figures that emphasize the importance of recognizing depressions that have a high potential for self-destruction. Every physician should, therefore, be familiar with the few clues we possess to identify those patients who intend to end their lives. Some of the questions that may be broached in the interview regarding depression were listed earlier (page 1311). Physicians should also be aware that the majority of suicides are accomplished by taking an overdose of prescribed medications, for which reason caution needs to be exercised in their prescription and administration in depressed patients.

Current opinion, summarized by Mann, indicates that suicidal intent represents a special form of depression, or an important variant of it, and that certain individuals are by nature susceptible as a result of biologic factors. In other words, suicide is not simply a cognitive response to extreme stress or despondency. There is no way for the authors to judge this view, but it seems correct and proponents have pointed to particular indices of serotonin function that differ between depressed individuals who attempt suicide and those who do not. It has also been observed that the inception of modern antidepressant medications has not greatly altered the rate of suicide among depressed patients. Manic-depressive illness, endogenous depression, depression resulting from a debilitating disease (particularly Huntington disease, cancer, and AIDS), pathologic grief, and depression in an alcoholic or schizophrenic all carry the risk of suicide. In manic-depressive disease and endogenous depression, the risk of suicide over the lifetime of the patient is about 15 percent (Guze and Robins). In Robins’ series of 134 patients who committed suicide, 47 percent had a known depressive illness and 25 percent were alcoholic. Other series have recorded even higher rates of depression, alcoholism, and other forms of drug abuse (see Andreasen and Black).

Most suicides are planned, not impulsive. Furthermore, the intention of committing suicide is more often than not communicated to someone significant in the patient’s life. In Robins’ series, 4 out of 5 patients had made medical contact in the year before death. The message may be in the form of a direct verbal statement of intent, or it may be indirect, such as giving away a treasured possession or revising a will. It is known that successful suicide is three times more common in men than in women and particularly common among men over 40 years of age. Patients with a history of suicide in either mother or father carry a higher risk than those without such a history. A previous suicide attempt adds to the risk. Experience has instructed that important deterrents to suicide are devout Catholicism or comparable religious belief (suicide is a sin), concern about the suffering it would cause the family, and fear of death sincerely expressed by the patient. However, no single one of these attributes stands out as entirely predictive of suicide. As a consequence, one is left with clinical judgment and an index of suspicion as the main guides. The only rule of thumb is that all suicidal threats are to be taken seriously and all patients who threaten to kill themselves should be evaluated by a psychiatrist.

Some physicians are reluctant to question depressed patients about the presence of suicidal thoughts on the grounds that this might upset them. More likely it is the physician who is upset by this questioning, for surely the mention of suicide will not alarm persons who are determined to end their lives or offend those with no such intention. Rather, a query of this type is apt to be appreciated by the depressed patient because it expresses the physician’s concern and indicates that the patient’s behavior is taken seriously. Should a patient’s manner or conversation raise a suspicion of suicidal intent, the issue should be quickly taken up by the physician. If the suicidal patient refuses hospitalization, the family should be consulted, along with an intimate friend or clergyman if appropriate, to urge the patient’s cooperation. Should all efforts fail, the only recourse may be commitment to a psychiatric ward. Although an action of this sort is bound to be stressful for all concerned, hard feelings engendered by a short period of enforced confinement vanish in time; but those who mourn the loss of a loved one through a preventable suicide are apt to be unforgiving.

Among patients who have been hospitalized because of a preoccupation with suicide, a particular danger attends the phase of recovery from depression, when the physician may be lulled into a false sense of security. In either case, a psychiatrist should assume the responsibility for setting up a program of therapy and arranging for transfer to a psychiatric ward if this is necessary, or for outpatient treatment. For the depressed patient with terminal disease, the authors have taken the personal position of providing comfort by all possible means but not in assisting the patient to commit suicide.

THE SCHIZOPHRENIAS AND PARANOID STATES

SCHIZOPHRENIA

Schizophrenia is among the most serious of all unsolved diseases. This was the opinion expressed 50 years ago in Medical Research: A Mid-Century Survey, sponsored by the American Foundation. Because of a worldwide lifetime prevalence of about 0.85 percent and particularly because of its onset early in life, its chronicity, and the associated social, vocational, and personal disabilities, the same conclusion is justified today (Carpenter and Buchanan).

Definitions Neurologists and psychiatrists currently accept the idea that schizophrenia comprises a group of closely related disorders characterized by a particular type of disordered thinking, affect, and behavior. The syndrome by which these disorders manifest themselves differ from those of delirium, confusional states, dementia, and depression in ways that will become clear in the following pages. Unfortunately, the diagnosis of schizophrenia depends on the recognition of characteristic psychologic disturbances largely unsupported by physical findings and laboratory data. This inevitably results in a certain diagnostic imprecision. In other words, any group of patients classified as schizophrenic will to some extent be “contaminated” by patients with diseases that only resemble schizophrenia, whereas variant or incomplete cases of schizophrenia may not have been included. Moreover, there is not full agreement as to whether all the conditions called schizophrenic are the expression of a single disease process. In America, for example, paranoid schizophrenia is usually considered to be a subtype of the common syndrome, whereas in some parts of Europe it is thought to be a separate disease.

Historical Background Present views of the disease now called schizophrenia originated with Emil Kraepelin, a Munich psychiatrist, who first clearly separated it from manic-depressive psychosis. He called it dementia praecox (adopting the term introduced earlier by Morel) to refer to a deterioration of mental function at an early age, from a previous level of normalcy. At first, Kraepelin believed that “catatonia” and “hebephrenia,” which had previously been described by Kahlbaum and by Hecker, respectively, as well as the paranoid form of schizophrenia, were separate diseases, but later, by 1898, he had concluded that these were all subtypes of a single disease. He emphasized an onset in adolescence or early adult life and a chronic course, often ending in marked deterioration of personality as the defining attributes of all forms of the disease. Early in the twentieth century, the Swiss psychiatrist Eugen Bleuler substituted the term schizophrenia for dementia praecox. This was an improvement insofar as the term dementia was already being used to specify the clinical effects of another category of disease, but unfortunately the new name implied a “split personality” or “split mind.” By the “splitting” of psychic functions, Bleuler meant the lack of correspondence between ideation and emotional display—the inappropriateness of the patient’s affect in relation to his thoughts and behavior. By contrast, in manic-depressive disease, the patient’s mood and affect accurately express his morbid thoughts. Bleuler also introduced the terms autism (“thinking divorced from reality”) as an aspect of the thought disorder.

Bleuler believed that all the schizophrenic syndromes were composed of primary or basic symptoms, summarized by some authors as the “four A’s” (loose associations, flat affect, ambivalence, and autism), and of secondary or “partial phenomena” such as delusions, hallucinations, negativism, stupor, etc. However interesting this formulation proved to be, the psychologic abnormalities are so difficult to define precisely that this arbitrary division has been of only mnemonic value.

Other early theories were those of Adolf Meyer and Sigmund Freud. Meyer, who introduced the “psychobiologic approach” to psychiatry, sought the origins of schizophrenia, as well as other psychiatric syndromes, in the personal and medical history of patients emphasizing particularly their habitual reactions to life events. Freud viewed schizophrenia as a manifestation of a “weak ego” and an inability to use the ego defenses to control anxiety and instinctual forces—the result of a fixation of libido at an early (“narcissistic”) stage of psychosexual development. None of these theories has been corroborated, and none ever gained wide acceptance.

In 1937, Langfeldt advanced the important concept that schizophrenia consists principally of two different types of psychosis: (1) one that corresponds to the disease considered briefly earlier, i.e., Kraepelin’s dementia praecox and Bleuler’s schizophrenia (characterized essentially by early onset of anhedonia and asociality and by a poor prognosis), and (2) a type that occurs acutely, on a background of a stable premorbid personality, often with clouding of consciousness, prominent delusions and hallucinations, and demonstrable precipitating factors. For the second type, which could be a manifestation of several diseases, Langfeldt proposed the term schizophreniform psychosis. Cases of the latter type tend to have a favorable prognosis. Subsequent studies have validated this distinction, as indicated further on.

A more contemporary biologic approach to schizophrenia has involved the isolation of its many persistent mental and behavioral features into three clusters: (1) so-called negative symptoms of diminished psychomotor activity (poverty of speech and spontaneous movement, flatness of affect); (2) a “disorganization” syndrome, or thought disorder (fragmentation of ideas, loosening of associations, tangentiality, and inappropriate emotional expression); and (3) reality distortion, comprising hallucinations and delusions or so-called positive symptoms (Liddle; Liddle and Barnes). The separation of behavior into “positive” and “negative” symptoms was believed to be useful in distinguishing among the types of schizophrenia and perhaps to align the mental status with conventional physiologic analysis but this view is an oversimplification (see review by Andreasen). Although there is still disagreement as to whether each of these groups is primary or secondary, positive or negative, they have the value of lending themselves to objective study and correlation with other biologic measures.
Clinical Syndrome of Schizophrenia

The central abnormalities in schizophrenia are hallucinations and a special disorder in the perception of one’s self in relation to the external world. It is unlike the condition that prevails in delirium and other confusional states, dementia, and depression. Some patients with chronic schizophrenia, before the onset of a flagrant psychosis or when in remission, show none of the schneiderian first-rank symptoms and—during brief testing of mental status—might even pass for normal. But on long-term observation they are vague and preoccupied with their own thoughts. They seem unable to think in the abstract, to understand fully figurative statements such as proverbs, or to separate relevant from irrelevant data. There is what has been called a circumstantiality and tangentiality about their remarks. They fail to communicate their ideas clearly. Their thinking no longer respects the logical limits of time and space. Parts are confused with the whole or are clustered together or condensed in an illogical way. Opposites may be considered as identical, and conceptual relationships are distorted. In an analysis of a problem or a situation, there is a tendency to be overinclusive rather than underinclusive (as happens in dementia). In conversation and in writing, the trend of an argument or thought sequence is often interrupted abruptly, with a resulting disorder of verbal communication. Such disorders of thinking are reflected in the patient’s behavior. There is over time a general deterioration in functioning, social withdrawal and at times bizarre actions, idleness, self-absorption, and aimlessness.

In more severely affected schizophrenic patients, thinking is even more disintegrated. They appear to be totally preoccupied with their inner psychic life (thus the early use of the term autism) and may do no more than utter a series of meaningless phrases or neologisms, or their speech may be reduced to a nonsensical “word salad.” They are unable to attend to any task or to concentrate, and their performance is interrupted by sudden “blocking” or by insertion of some extraneous idea or inexplicable act, somewhat like that observed in a severely confused or delirious patient. At times these patients are talkative and exhibit odd behavior; at other times they are quiet and idle; in the extreme, the patients are mute or assume and maintain imposed postures or remain immobile (catatpsy). With remission, they may remember much of what has happened or they may have only fragmentary memories of events that occurred.

Typical of schizophrenia is the patient’s expression of remarkably unusual experiences and ideas. The patient may express the thought that his body is somehow separated from his mind, that he does feel as if he is himself, that his body belongs to someone else, or that he is unsure of his own identity or even sex. These experiences have been called depersonalization. Thought insertion, wherein it seems to the patient that an idea has been implanted into his mind, or thought withdrawal, wherein an idea has been extracted from his mind by an outside agency, are other parts of this problem. Closely related, and characteristic of schizophrenia, are ideas of being under the control of some external agency or being made to speak or act in ways that are dictated by others, often through the medium of radar, telepathy, or the internet (passivity feelings). Frequently, there are ideas of reference—that the remarks or actions of others are subtly or overtly directed to the patient. Finally, the patient may feel that the world about him is changed or unnatural, or his perception of time may be altered, not in a brief episode like the jamais vu of a temporal lobe seizure, but continuously; this is the phenomenon of derealization.

Auditory hallucinations are frequent and a core feature of the classic illness. They consist of voices that comment on the patient’s character and activities and are usually accusatory, threatening, or claiming control of the patient’s actions. The voices may or may not be recognized; they may belong to one person or two or more persons who converse with the patient or with one another. Seldom can the voices be localized to a point outside the patient. Instead, they seem to come from within the patient, so that at times they cannot be distinguished from his own feelings and thoughts. Certain somatic hallucinations and delusions may predominate in any one individual. Visual, olfactory, and other types of hallucinations also occur but are much less frequent. The patient believes in the reality of these hallucinations and often weaves them into a delusional system.

It should be reiterated here that hallucinations are a feature of a number of neurologic processes but in most, visual hallucinations predominate whereas auditory hallucinations are the hallmark of schizophrenia. Of interest in this regard is “The Report on the Cens of Hallucinations” by Sidgwick in 1894 that suggested (as cited by Frith) that almost one in ten ostensibly normal respondents had experienced hallucinations, mostly visual. The illnesses in which hallucinations and delusions are prominent, for example hallucinogenic drug ingestion and the Charles Bonnet syndrome (see pages 220 and 405), have been reviewed by Frith.

Of interest has been the belated affirmation of the importance of negative symptoms in schizophrenia. Liddle and Barnes, looking objectively at all aspects of schizophrenic thought and behavior, divided them into four groups: (1) flat affect, diminution in expressive gestures, latency of response, reduced spontaneous movements, apathy, restricted recreational activities, inability to feel intimate or close, and motor retardation. These negative symptoms,
which have resemblances to frontal lobe behavioral syndromes, correlate with reduced blood flow in the frontal lobes and a poor prognosis: (2) disorganization of thought, incoherence, inappropriate affect, illogicality, bizarre behavior, aggression, agitation, and tangentiality. These abnormalities are nonfrontal: (3) hallucinations and delusions that the patient’s mind is being read and that thoughts are being extracted from his mind or being controlled or broadcasted; (4) suspicion, hostility, and delusions of reference. These authors also found an overlap of symptoms from one group of symptoms to another, i.e., the four syndromes can coexist in various combinations. However valid such subdivisions prove to be, they offer a more systematic neurologic approach to schizophrenia and direct attention to the functional anatomy and physiology of particular neuronal systems in the brain (see further on; also Friston et al).

The behavior of the schizophrenic who experiences these ideas and feelings is correspondingly altered. Early in the course of the illness, normal activities may be slowed or interrupted. No longer does the patient function properly in school or at work. Associates and relatives are likely to find the patient’s complaints and ideas disturbing. The patient may be idle for long periods—preoccupied with inner ruminations—and may withdraw socially. A panic or frenzy of excitement may lead to an emergency ward visit (a high degree of anxiety occurring for the first time in a young person should always raise the suspicion of a developing schizophrenia); or the patient may become mute and immobile, i.e., catatonic. Attacks of catatonia are infrequent, but lack of will, drive, assertiveness, etc., are characteristic of the disease. Ultimately a deteriorated and dilapidated state occurs which, in the extreme, results in an unkempt and malnourished state with which the public unfortunately associates schizophrenia. Some individuals of this type roam the streets and live in appalling conditions on the fringes of society where they are subject to the criminal behavior of others.

Much has been made of the change in affect observed in schizophrenic patients. Usually the affect is said to be “flat,” i.e., the patient’s manner is bland and apathetic; he may casually express ideas that would be disturbing to a normal person, even smiling or laughing over a morbid idea. To the authors, this has not been an impressive feature of the illness. More often one observes agitation and an appropriate display of emotion in response to a threatening hallucination or delusion, although as the illness advances increasing indifference and preoccupation appear, as though the patient had become inured to the abnormal thoughts and feelings.

That schizophrenia of all types carries a significant risk of suicide is not generally appreciated. In a 40-year follow-up study of schizophrenic and manic-depressive patients, Winokur and Tsuang found that in each group the proportion of patients who had committed suicide was the same (about 10 percent). Suicide occurs most often among young schizophrenic patients living apart from their families who are frightened and overwhelmed by their symptoms and experience the difficulties of independent existence. Sometimes suicide is a response to terrifying and commanding vocal hallucinations. The schizophrenic patient may also be homicidal, usually acting upon a delusion that he or she has been wronged by the victim. Incidents of this type are unpredictable, but the presence of escalating paranoia should be a warning.

Finally, whether a genuine dementia results from chronic schizophrenia has been much debated over the years. The notion of this type of “dementia praecox” was discarded but clinicians continue to encounter cases of progressive generalization and sometimes severe intellectual impairment in both acute and long-standing cases of schizophrenia; this has been true before and after the modern era of therapeutics. The problem has been highlighted by de Vries and colleagues who analyzed what they considered to be a frontotemporal type of dementia in 8 patients after 9 to 30 years of schizophrenia; they found minor changes on computed tomography (CT) scans, and frontal or temporal hypoperfusion on single photon emission computed tomography (SPECT).

Diagnostic Criteria

Included in the early definitions of the disease, both of Kraepelin and of Bleuler, were a characteristic premorbid personality, an insidious onset of the more flagrant symptoms in adolescence or early adult life, and a chronic but fluctuating course with a tendency to progressive deterioration. Both regarded hallucinations and delusions as secondary or accessory symptoms that could be absent, as in their “simple schizophrenia.” They emphasized the absence of primary disturbances of perception, orientation, memory, and other cognitive functions, which played such a large role in other cerebral diseases. Embodied in both their definitions was the concept of disease characterized by a poor prognosis and, as stated earlier, a unique constellation of symptoms different from those of delirium, confusion, depression, mania, dementia—the other manifestations of brain diseases.

Attempts to apply these diagnostic criteria initially met with difficulty, especially when hallucinations and delusions were absent. In order to overcome this, Schneider proposed that the distinction between primary and accessory manifestations be abandoned. He attached more importance and reliability to the occurrence of auditory hallucinations, perceptual delusions (misinterpretation of what the patient hears and feels), and disturbances of thinking, often reflected in the experience that one’s thoughts and actions are being broadcast and are not one’s own but are under the influence of some outside agency (experiences of alienation and influence). This constellation of symptoms, which was more precise and easy to recognize, came to be known as Schneider’s first-rank symptoms of active schizophrenia. Strict adherence to Schneider’s diagnostic criteria, when applied to a group of patients admitted to the hospital with a diagnosis of schizophrenia, served to distinguish two groups of patients—those with and those without first-rank symptoms (Taylor). Those without hallucinations, delusions, and thought control or projection responded more poorly to treatment and required a more prolonged period in the hospital and higher doses of neuroleptic drugs than did those with these features. The two groups correspond closely to two categories of schizophrenic disorders recognized by Robins and Guze on the basis of prognosis. The Schneider-positive, poor-prognosis schizophrenia (also referred to in older literature as nuclear or process schizophrenia) corresponds closely to korsakian schizophrenia; many of the Schneider-negative patients with good prognosis are probably suffering from some other nonpsychotic illness or schizophreniform illness, or manic-depressive disease (see Chap. 57).

Feighner and colleagues, who drew up a set of diagnostic criteria for research in the major psychiatric syndromes [which were subsequently incorporated in successive editions of the Diagnostic and Statistical Manual of Mental Disorders (DSM)], stated that the diagnosis of schizophrenia is tenable only in the presence of (1) a chronic illness of at least 6 months’ duration and a failure (after an acute episode) to return to the premorbid level of psychosocial adjustment, (2) delusions or hallucinations without significant confusion or disorientation (i.e., without clouding of consciousness),
such as most instances to be "disorganized, confused, and ideationally fluid"

means of formal psychologic tests (Solovay et al.), has shown it in most instances to be "disorganized, confused, and ideationally fluid with many peculiar words and phrases." This is a refinement of Bleuler's characterization of "loosening of associations." Terms such as schizoid, schizotypal, latent, or borderline schizophrenia have been applied to this form of the illness. In many cases this seems to be an extension of the childhood schizoid personality traits into adolescence. Eventually, in most cases an outbreak of flagrant hallucinations and delusions occurs—an acute schizophrenic episode that brings the patient to the attention of a physician. The patient usually needs to be hospitalized and medicated because of a suicidal or, rarely, homicidal attempt or some other unexpected behavior. As a rule, a remission follows within a few weeks or months, during which the patient is again able to function, but at a level below that which is expected on the basis of his natural abilities and intelligence, and he continues to be lacking in drive, initiative, and enterprise, much as he was before the outbreak.

These patients may attract notice in middle and high school because they behave in an odd manner, tending to remain by themselves ("loners"), making no effort to adjust to a social group at school or to find work, have dates, or later, to establish a family unit. If support and protection is not provided, such persons drift from one menial job to another, always shy, withdrawn, and relatively indifferent to their surroundings.

**Catatonic Schizophrenia** This, the most readily differentiated type of schizophrenia, is now quite rare. Characterized by an extreme diminution in psychomotor activity, it was originally described by Kahlbaum and considered to be a mental disturbance sui generis until Kraepelin recognized it as another form of schizophrenia. In about 60 percent of cases the onset is relatively acute. In the remainder, after a long prodrome of slackening interest, apathy, and dreamy preoccupation, a state of dull stupor supervenes, with mutism, inactivity, refusal of food, and a tendency to maintain one position "like a mummy" (catalepsy). The facial expression is vacant, the lips are pursed; the patient lies supine without motion or sits for hours with hands on knees and head bowed (a form of catalepsy). If a limb is lifted by the examiner, it will sometimes be held in that position for hours (flexibilis cerea). Urine and feces are retained or there is incontinence. The patient may require tube-feeding (or will eat mechanically) and has to be dressed and undressed. Pinprick or pinch induces no reaction. Extreme "negativism," every command being resisted, characterizes some cases. Echolalia and echopraxia are observed occasionally. Yet these patients may be fully aware of what is said to them or happening around them and will reproduce much of this information during a later spontaneous remission or one induced by intravenous sodium amytal or midazolam. Even if untreated, the patient, after weeks or months in this state, begins to talk and act more normally, and there is then rapid recovery. In certain phases of catatonia there may be a period of excitement and impulsivity, during which the patient may be suicidal or homicidal.

As mentioned, for reasons that are unclear, this form of schizophrenia is now seen infrequently, and there is increasing recognition of the fact that its catatonic features are often manifestations of a depressive illness rather than of schizophrenia.

**Disorganized, or Hebephrenic, Schizophrenia** This was believed by Kraepelin to be a particularly malignant form of the disease. It tends to occur at an earlier age than the other varieties, hence the prefix hebe ("youth"). The thought disorder is pronounced—there is a striking incoherence of ideas and a grossly inappropriate affect; the frequent occurrence of hallucinations and delusions leaves little doubt that the patient is psychotic. The visual and auditory illusions and hallucinations are usually more in the nature of symbolic interpretations than abnormal perceptions. Kraepelin remarked on the changeable, fantastic, and bizarre character of the delusions. Motor symptoms, in the form of grimacing, stereotyped mannerisms, and other oddities of behavior, are prominent. In hebephrenic patients, since early life, there is likely to have been a history of tantrums and of being overly pious, shy, fearful, solitary, conscientious, and idealistic—traits that may have marked these individuals as odd. This latter state corresponds to what was referred to earlier on as a schizoid personality but could just as well represent the early phase of the disease itself (see Chap. 56).

**Paranoid Schizophrenia** This is one of the most frequent and well-circumscribed types. The mean age of onset is in the early forties, much later than that of the preceding types (Winokur). The central feature is the preoccupation with one or more delusions related to a single or to a limited ensemble of themes, accompanied
by auditory hallucinations. More often than not, the delusional hallucinatory content is persecutory, but it may also be religious, depressive, grandiose, or bizarrely hypochondriacal in nature. Delusional jealousy may be added. Many such patients settle into a chronic hallucinatory psychosis with disorders of thinking featuring mistrust and suspiciousness. They appear cold, aloof, and indifferent.

Some European psychiatrists, impressed with the lack of schizoid traits in the premorbid period and late onset have insisted that paranoid schizophrenia is a separate disease. The studies of Rosenthal and colleagues and the clinical and family studies of Winokur tend to bear them out in that simple, catatonic, and hebephrenic types have different characteristics from paranoid schizophrenia.

There are, of course, other psychiatric illnesses in which paranoid delusions appear, notably manic-depressive psychosis, dementia, and delirium. Alcoholic auditory hallucinosis also stands as a separate illness (page 1008). There is, in addition, a special form of delusional disorder (paranoia) in which the individual is consumed by a single persecutory, grandiose, or amorous delusional system without any other disorder of thinking. An exotic form is known as folie à deux, in which two closely related persons share a delusional system. These types of paranoia are discussed further on in this chapter.

**Acute Schizophreniform Psychosis** A special problem arises in the diagnosis of a rapidly evolving psychotic syndrome with florid hallucinations or delusions that clear in several weeks or less, with or without treatment. This most often turns out to be the initial attack of mania or of intoxication with a psychotropically hallucinogenic drug, for which reason it is not accorded a separate subtype of schizophrenia. The resolution of the diagnostic dilemma often depends on the patient’s premorbid status and the course of events that follows the acute episode. This topic is discussed further on under “Diagnosis.”

**Remissions and Exacerbations** Some schizophrenic patients are subject to periodic exacerbations of their illness, sometimes at regular intervals, as if the process was a metabolic disorder. Remissions that allow some degree of functioning in society are more frequent and lasting when medication is given and long institutionalization is avoided. A small proportion of patients (about 10 percent), after an acute schizophrenic episode, have a long-lasting and fairly complete remission before lapsing into a chronic form of the illness. Unfortunately, these latter patients, at the time of their acute psychosis, cannot be distinguished from those few who will have a permanent remission.

Modern therapeutic programs have vastly reduced the number of patients in mental hospitals. However, readmission rates have also risen (revolving-door phenomenon), and the total number of very young and very old patients in hospitals has even increased slightly. The life expectancy of schizophrenic patients is somewhat reduced, possibly because of the malnutrition, neglect, and exposure to infections that occur in some public institutions and from living on the streets or in marginal circumstances.

**Neurologic and Neuropsychologic Abnormalities in Schizophrenia**

The early findings of Kraepelin and of Bleuler, that many schizophrenic patients will, on detailed examination, show some neurologic abnormalities, have been substantiated by Stevens, Kennard, Hertzig and Birch, Tucker and colleagues, and Woods. They all found a much higher frequency of “soft neurologic signs” in schizophrenic patients than they did in a healthy population. The signs to which they refer include inattentiveness, inattentiveness and graphesthesia, sensory extinction, hyperreflexia and hyporeflexia, slight tendency to grasping, mild impairment of coordination and disturbances of balance, abnormal (choreiform) movements, abnormalities of motor activity, adventitious and over-flow movements, anisocoria, slight esotropia, and faults in visual-auditory integration. Signs of this type were noted in 50 percent of patients and correlated with the degree of cognitive disorder. Also evident in about one half of schizophrenic patients are subtle defects in ocular tracking movements (Levin et al). These take the form mainly of slowed smooth pursuit and intrusions of saccades during pursuit; some relatives of schizophrenic patients also show these eye signs when carefully tested. In contrast, “hard neurologic signs” (such as unilateral motor or sensory defects) are not seen unless they are due to an engrafted neurologic disease. Electroencephalographic (EEG) abnormalities have been detected in about one third of patients but are generally minor; their meaning is uncertain, especially if they have occurred after long-standing treatment. When these were the focus of research in the past, they were more frequent in the group of schizophrenic patients who had a positive family history and in those with enlarged ventricles (Murray et al).

Sophisticated psychometric testing has disclosed abnormalities not so much in intelligence and memory (which are only slightly reduced in 20 to 30 percent of cases) as in other psychologic functions. Alertness is not impaired, but the ability to maintain attention, as measured by continuous performance tasks, is reduced (Seidman). In tests of verbal and visual pattern learning, problem solving, and memorizing, Cutting found a surprising degree of impairment in both acute and chronic schizophrenic patients (and in patients with retarded depression) not attributable to electroconvulsive therapy, seizures, drugs, or other diseases. In the acute schizophrenic patient, verbal memory was more affected than visual pattern memory, in agreement with the findings of Flor-Henry that left-hemispheric functions are more reduced than rightsided ones. Yet, in the chronic schizophrenia, there was evidence of bihemispherical impairment.

**Theories of Causation and Mechanism**

Although there is no universal agreement as to the cause of the disease, an increasing weight of evidence favors an interaction between a genetic predisposition and one or more early developmental events. One widely held contemporary hypothesis is that this disease reflects an underlying developmental disorder, determined either genetically or because of an environmental insult, leading to abnormalities of synaptic connectivity, prominently affecting the hippocampus and prefrontal cortex. The evidence supporting this view is summarized briefly later. More detailed analysis of potential causes than can be given here may be found in reviews of Waddington, Carpenter and Buchanan, Harrison, Pearlson, and Freedman.

**Genetic Factors** Several authors have estimated that genetic factors can account for upward of 80 percent of the risk of developing schizophrenia. The early studies of Kallmann showed that the frequency of disease in 5000 siblings of schizophrenic patients was
11 percent, in contrast to slightly less than 1 percent in the general population. In 90 sets of fraternal twins of whom one had schizophrenia, the incidence of disease in the other twin was also 11 percent, the same as in nontwin siblings; however, in 62 sets of monozygotic twins, the incidence in the second twin was 68 percent. The risk that a child of a schizophrenic parent will develop schizophrenia is the same as that for the sibling of a schizophrenic patient (i.e., 11 percent); if one sibling and one parent have schizophrenia, the risk is 17 percent; if both parents are schizophrenic, the chances are 46 percent that the child will have the disease. Subsequent family and twin studies have repeatedly confirmed these findings (see Goodwin and Guze for a more complete tabulation). It is noteworthy that the penetrance of this trait appears to be less than it is for manic-depressive disease.

While the importance of genetic factors in the etiology of schizophrenia is undeniable, a mendelian pattern of inheritance has not been determined. Within the last several years, polymorphisms in several genes have been implicated as risk factors for schizophrenia. Such genes include those expressing neuregulin, dysbindin, COMT (catechol-O-methyltransferase), proline dehydrogenase, and DISC1 ("disrupted in schizophrenia 1"; Harrison and Owen, O'Donovan et al).

The studies implicating these genes must be interpreted cautiously because the functional significance, if any, of the allelic variants are not defined. Nonetheless, considered together, these findings point to disorders both of neuronal development and neurotransmission. Further supporting this view is the provocative finding that allelic variants associated with specific neurotransmitter systems (in the genes that code for serotonin receptors and COMT) are overrepresented in schizophrenia; these are more compelling than the aforementioned ones because the genetic variants have well-defined functional consequences. A summary of the genetic studies to date is given by Harrison and Owen and by O'Donovan et al.

**Environmental and Developmental Aspects** There continues to be debate concerning the relative importance of genetic versus environmental factors in the causation of the disease. The lack of complete concordance between monozygotic twins and the fact that approximately 80 percent of schizophrenic patients have no other family members with the disease indicate that factors other than genetic ones probably play a role. Some of these appear to be early events that occur *in utero* or infancy and alter normal developmental programs.

The neuropsychiatric literature contains tentative and only circumstantial evidence that schizophrenia is associated with brain injury during the intrauterine or neonatal period. Reportedly, there is an increased incidence of obstetrical complications during the gestational period and birth of schizophrenic patients. Also consistent with an early adverse environmental factor is the observation by several groups that in the northern latitudes, more schizophrenic persons are born in the winter months and to women who were exposed to influenza during midpregnancy—inviting speculation that a viral infection may have damaged the fetal brain. Mortenson and colleagues found that being born in an urban region, particularly in February or March, carried with it a higher risk for developing the disease than having an affected parent or sibling. They suggested that these inexplicable demographic features accounted for more cases than did inheritance. Among 5362 infants who were followed prospectively since their birth in 1946 by Jones and colleagues, the 30 individuals who later developed schizophrenia had been delayed in the attainment of motor milestones and speech and exhibited greater social withdrawal and schoolroom anxiety as well as lower scholastic achievement. Thus it appears that schizophrenic patients are not entirely normal in early childhood, but whether their abnormalities are already early manifestations of schizophrenia or risk factors for the disease has not been determined.

**Neuropathologic, Brain Imaging, and Neurophysiologic Findings** Notably lacking in all the previously described reports of developmental changes are neuropathologic data. Dunlap, in 1928, in a critical analysis, repudiated all earlier interpretations of cellular alterations that had been reported in the brains of schizophrenic patients. He pointed out that many of them, such as dark “sclerotic” nerve cells, were artifacts and that the presence of lipofuscin was a non-specific age change. He also asserted that the neuronal loss described by Alzheimer was based on impression and could not be corroborated by quantitative methods. Similarly, the claim of Oscar Vogt of neuronal loss in the cortex was rejected by his contemporaries, Spielmeyer and Scholz, who were unable to find any consistent cellular abnormality in schizophrenia. Spielmeyer, in a critical study of the problem in 1930, concluded that such changes as had been described up to that time could not be clearly distinguished from the normal, and that the more marked changes in some cases were likely due to coincidental causes (age, complicating disease, etc.). Correllas, on the basis of yet another thorough review of the neuropathologic data in 1976, found no reason to deviate from Spielmeyer’s view. The uncertain neuropathologic findings were responsible for the enigmatic categorization of schizophrenia as a “functional” disorder, i.e., a disorder with no structural basis.

Nonetheless, there has been a general sense that the number of neurons in the gray matter is normal, but the pyramidal cells are smaller and more densely packed, resulting in a thinning of laminae II and III. These cytoarchitectonic changes have been the most difficult to interpret and to confirm. Capricious methods such as the rapid Golgi stain indicate that density of dendritic spines is decreased in the frontal and temporal cortex of chronic schizophrenic patients.

A number of more contemporary reports using special cell-labeling studies have found cytoarchitectonic abnormalities in the brains of schizophrenic patients. For example, Akbarian and colleagues, following previous similar findings, have described an aberrant distribution of interstitial neurons in the frontal lobe white matter. These cells have their origin in the embryologic subplate that guides neuronal migration, and the inference is that the abnormally migrating cells have formed aberrant neuronal connections. Benes and colleagues observed that the number of small neurons was reduced in at least one layer (usually layer II) of the anterior cingulate cortex. These are gamma aminobutyric acid (GABA)-releasing (inhibitory) neurons. She also noted that the arrays of macrocolumns of cortical neurons were smaller in the occipital lobes (vertical axons increased in number), but without gliosis. More recent studies have also described a paucity of GABA-ergic, inhibitory interneurons (so-called chandelier cells) in the prefrontal cortex (Woo et al). These observations suggest a developmental rather than an acquired lesion, and the absence of gliosis supports but does not prove that the developmental disorder occurs prenatally.

The advent of CT and subsequently of magnetic resonance imaging (MRI) of the brain provided a new stimulus to the ana-
tonic study of schizophrenia. Johnstone and coworkers were the first to describe ventricular enlargement and sulcal widening in 18 patients and correlate these findings with dulling of intellect and affect. In a study of 58 chronic schizophrenics under the age of 50 years, Weinberger and colleagues found enlargement of the lateral ventricles in 40 percent. In 9 of 11 CT studies, the third ventricle was found to be enlarged, and in 14 of 17 studies, the sulci were widened. In 15 pairs of monozygotic twins, one of whom had schizophrenia, the anterior hippocampi were found to be smaller and the lateral and third ventricles larger in the affected twin (Suddath et al). Shenton and colleagues demonstrated a reduction in the volume of gray matter in the posterior part of the left superior temporal gyrus, which includes Heschl’s gyri and the planum temporale. The degree of volumetric reduction correlated roughly with the severity of the thought disorder. A reduction in volume of the superior temporal gyrus has also been associated with the occurrence of auditory hallucinations (Barta et al). Other MRI studies have shown a volumetric change in the gray matter of the left hippocampus, parahippocampal gyrus, and amygdala (in righthanded patients). Equally compelling is the finding that young individuals having two or more relatives with the disease, and therefore being at risk for developing schizophrenia, have certain volumetric brain changes detected by imaging studies (Lawrie et al). In unaffected relatives, the left hippocampal-amygdaloid region was smaller than in healthy people but slightly larger than in affected relatives.

In an attempt to organize the neuroradiologic findings, Murray and coworkers have raised the possibility that there are two types of this disease—one with ventricular enlargement and a negative family history and the other with normal ventricles and a positive family history. In the first group of sporadic, “acquired” schizophrenia, environmental factors, such as birth injury and EEG abnormalities (see later) were thought to be more frequent. In summarizing the many cerebral changes observed in schizophrenic patients, Harrison concluded that several are quite consistent. These include mild enlargement of the lateral and third ventricles; decreased cortical volume, perhaps disproportionate in the temporal lobe; and—microscopically—diminution in size of cortical and hippocampal neurons; a diminished number of neurons in the dorsal thalamus; and a notable absence of gliosis.

Detailed neuropsychologic testing has disclosed deficits in attention and abnormalities of the P300 waves (cortical “event-related” potentials). These deficits correlate with reduced cognitive activation activity in functional MRI. It is unclear, however, if these changes represent primary defects or are secondary to an inherent lack of motivation.

Attention has also been drawn to the regional alterations of cerebral blood flow in chronic stable schizophrenic patients, as revealed by positron emission tomography (PET) and functional MRI. Weinberger and colleagues and Liddle and Barnes have reported a decrease in blood flow in the prefrontal areas during cognitive performances. Friston and associates found consistent abnormalities in the left parahippocampal region in all forms of chronic schizophrenia. Studies of regional glucose metabolism and postmortem norepinephrine measurements have yielded equivocal data, although most patients show a reduction in glucose metabolism in the thalamus and frontal cortex. Several lines of investigation point to the medial part of the left temporal lobe and related limbic and frontal systems as being the focus of a developmental abnormality (see Tsuang et al and Friston et al for pertinent references). According to Sabri et al, the inconsistent findings on functional imaging may be accounted for by correlations between certain blood flow patterns and specific symptoms. For example, the formal thought disorder corresponded to increased flow in the frontal and temporal regions, while delusions and hallucinations were associated with reduced flow in the cingulate, left frontal, and temporal areas. Silbersweig et al have performed PET studies in schizophrenic patients while they were experiencing auditory hallucinations and found increased blood flow mainly in both thalami, left hippocampus, and right striatum, but also in the parahippocampal, orbitofrontal, and cingulate areas. One of their drug-naive patients with visual and auditory hallucinations showed activation in these regions.

Neurotransmitter Abnormalities When certain hallucinogens, such as mescaline and lysergic acid diethylamide (LSD), were first observed to induce hallucinations and abnormalities of thinking, it was hoped that they might provide experimental models of schizophrenia. This hope was never realized, but there are instances, difficult to interpret, in which these drugs have induced a prolonged relapse in a schizophrenic patient. Similarly, when methionine, a potent source of methyl groups, was observed to exacerbate the symptoms of some schizophrenic patients, it was thought that a primary metabolic fault had been discovered; increased serum concentrations of dimethoxyphenylethylamine and N-methylated indoleamines lent support to this idea. Again, none of these observations has been unequivocally corroborated.

The leading biochemical hypothesis has been based on the response of psychotic symptoms to phenothiazine medications, thereby implicating the dopaminergic system of the temporal lobe (see review by Carlson). The evidence for this is circumstantial but is supported by observations that antipsychotic drugs reduce the electrical activity of mesolimbic dopaminergic neurons in experimental models. Furthermore, there have been several demonstrations of increased concentrations of dopamine or its metabolite, homovanillic acid, in schizophrenic brains obtained at autopsy. The finding that dopamine receptors are organized in two systems, one limbic and the other cortical, has led to an expanded but purely speculative hypothesis that an excess of dopaminergic activity in the mesolimbic system gives rise to the positive symptoms of schizophrenia—i.e., psychosis—whereas a diminished activity in the mesocortical system accounts for the negative symptoms. The involvement of the mesolimbic system, which plays a role in attention, has prompted further speculation that the thought disorder of schizophrenia is attributable to a breakdown of the normal “filtering” of stimuli reaching cognition. As mentioned earlier, it has been found that a variant in the gene for COMT that enhances metabolism of dopamine is overrepresented in schizophrenia. This finding incriminates a disorder of dopaminergic neurotransmission in the pathophysiology of this disease (Egan et al).

As pointed out in the review by Freedman, however, the dopamine hypothesis has many weaknesses, the most prominent of which is the relative ineffectiveness of dopamine blocking drugs in alleviating many aspects of the disease. The complexity of dopamine systems and their interaction with other neurotransmitter circuits makes a simplistic mechanism unlikely.

More recently, an hypothesis based on changes in the serotonergic system has been proposed. As with the dopaminergic model, attention was drawn to mechanisms relating to serotonin when a new class of antipsychotics (clozapine, risperidone), which have effects on the latter system, were found to ameliorate the psychosis. Several groups have reported alterations in serotonin
receptors in the brains of schizophrenic patients (see later). A further connection is based on the finding by Williams and colleagues of an allelic variation in the gene on chromosome 13 encoding for a serotonin receptor (5-HT2A) that confers a susceptibility to schizophrenia. A similar finding has been reported in a Japanese population. The variation in this gene is not sufficient to explain the presence of the disease in any one individual, if for no other reason than that many patients who are homozygous for the suspect allele do not develop schizophrenia. Perhaps a nearby region relating to the receptor may be at fault through linkage disequilibrium (see commentary by Harrison and Geddes). A third hypothesis derives from the psychosis syndrome produced by chronic ingestion of phencyclidine (PCP), an N-methyl-D-aspartate (NMDA) antagonist. This implicates the glutaminergic system but it must be pointed out that the dopaminergic and glutaminergic systems converge on certain cortical neurons and that glutaminergic release is modulated in several places in the brain by dopamine.

A great variety of physiologic and endocrine differences between schizophrenic and healthy subjects have been claimed. None has proved to be significant. Since psychoses may complicate corticosteroid administration and certain endocrine disorders (Cushing syndrome, thyrotoxicosis, see later), there have been many attempts to uncover such abnormalities in the schizophrenic patient. All have failed.

Psychosocial Hypotheses The notion that psychosocial factors play an important role in the genesis of schizophrenia was a recurrent theme in older psychiatric writings but is now given little credence. Prominent in these early writings was Freud’s view, already mentioned, that the schizophrenic process represents a fixation at an early autoerotic stage of sexual development. There is no way of affirming or refuting this proposition. The same can be said for the many suggestions that disturbed intrafamily relationships engender schizophrenic traits or possibly provoke psychosis in persons who are genetically vulnerable. Behind all these suggestions was the notion that disturbed interpersonal relations in the family in some way interfered with the normal maturation of personality. Adolf Meyer believed that schizophrenia was a reaction to a series of traumatic life situations—a maladaptive response to some organic, psychologic, or sociologic factor. Others have stressed the importance of disturbed interpersonal relationships. However, with all these hypotheses, proof is lacking that such environmental factors are unique to the development of schizophrenia. Furthermore, the extent to which these aberrations of family relationships are primary or secondary cannot be ascertained.

The often-cited observations of Harlow on the deleterious effects of maternal and peer deprivation in primates opened the possibility that similar deprivations in humans may be responsible for the development of schizophrenia. However, such severe degrees of familial deprivation have rarely been documented in humans and when they were, as in some orphans, the effects were only transitory.

Diagnosis

From a neurologic standpoint, the main initial distinction to be made is between an acute schizophrenia-like psychosis (schizophreniform reaction; “good-prognosis” schizophrenia) and the chronic disease, schizophrenia (nuclear, or “process,” schizophrenia). The acute schizophreniform illness takes the form of a delusional-hallucinatory syndrome in which there is little if any disturbance of consciousness. Although such a syndrome is characteristic of schizophrenia, it may occur in the manic phase of manic-depressive disease, encephalitis, temporal lobe epilepsy, chronic amphetamine intoxication, withdrawal from alcohol after a sustained period of intoxication, and most often in the emergency department, PCP, angel dust, LSD, and other drug intoxications. On rare occasions it is seen with postpartum psychosis (see further on) and with certain endocrine and metabolic disorders, in which consciousness is not impaired. Whenever this syndrome is recognized, therefore, these several causes need to be differentiated. On our services, less than one out of five of the acute schizophreniform psychoses have proved to be due to the disease schizophrenia. This distinction is made by the premorbid history and the course of the illness. Restated, a longitudinal observation is necessary before concluding that a particular acute syndrome is due to schizophrenia. If the patient had been reclusive, withdrawn, and socially maladjusted does not seem to recover fully from the acute psychosis, then the diagnosis of schizophrenia is more likely. Lacking these features, and in particular with a full remission, one assumes the occurrence of hypomania or of a toxic-metabolic psychosis, which can usually be detected by laboratory screening for drugs and endocrine diseases. Only 10 percent of patients with classic schizophrenia will have such an acute episode. Adherence to the criteria enumerated earlier, particularly to those devised by Feighner and colleagues, will avoid most errors in diagnosis.

It is the present authors’ opinion that the status of acute schizophrenia and of the so-called schizothymic and schizoaffective states brings to light a crucial nosologic problem. Namely, is the traditional separation of depressive disease, manic-depressive disease, and schizophrenia biologically sound? The suggestion is that they are linked in some way by these transitional forms. Neurologists should keep an open mind about these and other theoretical problems that lack a firm genetic and neuropathologic basis.

In addition to the acute schizophreniform psychosis described earlier, the authors have encountered the greatest difficulties in the diagnosis of schizophrenia in the following clinical situations:

1. A patient with a healthy family and premorbid history with an acute illness having many of the typical features of schizophrenia but associated with confusion, forgetfulness, and/or clouding of consciousness. Mood change may be prominent. Thus the illness combines the features of an affective disorder, schizophrenia, and a confusional state. This syndrome is characteristic of chronic hallucinogenic drug use, particularly phencyclidine intoxication, corticosteroid psychosis (drug-induced or Cushing disease), thyrotoxic psychosis, puerperal psychosis, and combat fatigue of wartime. Usually recovery is complete, and schizophrenia is excluded by the fact that the patient remains well. This may be a form of “schizoaffective” disorder.

2. Adolescents and young adults whose social relationships are disorganized and who are unusually sensitive, resentful, rebellious, fearful, discouraged, in trouble with school authorities and the law, and using drugs. The latter may have caused seizures, hallucinations, and withdrawal symptoms or may have resulted in addiction. Such patients are usually classified as having a borderline personality or “character disorder” that appears to go back several years; if they are incorrigible, unable to profit by experience, amoral, and in trouble with social agencies, they are called sociopaths. This
type of personality disorder and social maladjustment usually turns out not to be schizophrenia.

3. There is another type of diagnostic problem, arising in an individual who has been only marginally competent because of personality problems and many vague neurotic and hypochondriacal symptoms, often requiring prolonged psychotherapy. Many such individuals will indeed be found to have simple schizophrenia (so-called “pseudoneurotic” form). Here errors in diagnosis usually result from a failure to assess mental status carefully and to ascertain the life profile of the disorder.

4. A chronic delusional-hallucinatory state in a chronic alcoholic patient (chronic alcoholic hallucinosis). Usually the history will disclose that the illness began when alcohol was withdrawn, after a period of sustained drinking, and at first took the form of an acute auditory hallucinosis, characterized by threatening, exteriorized auditory hallucinations to which the patient’s emotional reaction was appropriate. Only later do a few of these patients drift into a quiet hallucinatory, mildly paranoid state, with rather bland affect. Evidence of the prepsychotic schizophrenic personality cannot be detected, and there is usually no family history of schizophrenia. Cases of this type with which we are familiar had their onset between 45 and 50 years of age, i.e., much later than the usual age of onset of schizophrenia. This alcoholic, schizophrenia-like illness should be differentiated from the paranoid type of schizophrenia.

5. A patient who is confused or stuporous and seemingly catatonic-negativistic, refusing or unable to speak, to execute commands, or to be activated in any way. If signs of focal cerebral or brainstem disease are absent, one is tempted to make a diagnosis of catatonic schizophrenia, not appreciating that catatonia as a phenomenon may be indistinguishable from akinetic mutism (page 306); it may also appear with widespread disease of the association cortices and as mentioned earlier, with severe depression, certain confusional states, and hysteria. The error can be avoided if one makes diagnoses on the basis of positive findings, not on the absence of specific data. The authors have seen cases of hypoxic and other metabolic encephalopathies, Schilder disease, certain storage diseases, and Creutzfeldt-Jakob disease mistaken for schizophrenia because of failure to adhere to this principle.

6. A patient with temporal lobe epilepsy who, apart from intermittent psychomotor seizures, has long periods (weeks or months) of hallucinations, delusions, bizarre behavior, and disorganization of thinking. Such a mental disturbance often reflects the presence of a persistent state of temporal lobe seizures (temporal lobe status), which in some cases have been demonstrated by depth electrodes to originate in the amygdaloid or other medial temporal areas. The nature of the disturbances of emotionality and mentation in such patients, a somewhat controversial subject, is discussed in Chaps. 16 and 25.

7. Schizophrenic patients with prominent depressive symptoms who have made repeated suicide attempts pose an exceptionally difficult problem in diagnosis. They were referred to in the past as schizothymic, and to this day it is not certain whether they have schizophrenia, a relatively mild chronic depressive illness (dysthymia), depressive disease, or both schizophrenia and depression (“schizoaffective”). When in remission, patients with affective disorders are usually normal, whereas those with schizophrenia are not.

8. One should always be hesitant to make the diagnosis of schizophrenia during childhood, although such a diagnosis has been entertained in children who have a variety of developmental and adjustment problems and who at some time become psychotic, i.e., they become excited, depressed, or hallucinatory and express bizarre ideas. There is no evidence that such children go on to have schizophrenia later in life. And although what are thought to be “schizoid” traits may be recognized in childhood, a frank psychosis is hardly ever recorded at this age. Of particular importance in such children is to exclude the presence of metabolic errors, mental retardation, or an early-onset depressive illness. Similarly, childhood autism and particularly its milder forms (Asperger syndrome, page 889) should not be confused with schizophrenia. That the incidence of schizophrenia is not increased in the families of autistic children supports the idea that the two are separate diseases.

Treatment

The aims of treatment are to suppress psychotic symptoms, ameliorate the disorder of thinking and the apathetic state, prevent relapse, and optimize social adjustment. It is often possible, once the diagnosis of schizophrenia is established and the optimal regimen of medication decided upon, for a general physician to share the responsibility for following the patient with a psychiatric social worker or nurse. The physician soon becomes accustomed to the particular pattern of the patient’s behavior and can help support the patient and his family during difficult periods. Relapse with psychotic decompensation demands drug therapy, and if there is a hazard of injury or suicide or difficulty in management at home, hospitalization becomes necessary. Many general hospitals and specialized psychiatric institutions have facilities for the management of such patients; state hospitals and other institutions are able to provide long-term treatment. The aim of hospitalization is to protect the patient, relieve the family of the need for constant vigilance and supervision, and assure the administration of drugs until the exacerbation spends itself. Later, instead of mere custodial care, the patient needs a supervised program of planned activities, vocational and milieu therapy, often in a “halfway house,” which involves the patient as a contributing member during the more chronic phases of the disease. If medication is successful in preventing progressive decompensation, the patient can many times return to the family and community. It is invaluable to have a competent social worker or nurse maintain frequent contact with the patient and his family and assure continuity of medication.

The modern era of treatment of schizophrenia began in 1952, with the incidental demonstration by the French surgeon Henri Laborit of the antipsychotic properties of chlorpromazine. Subsequently, a large number of other phenothiazines have been used to treat chronic and acute psychosis. Treatment consists essentially of the administration of one of several similar antipsychotic medications. The various classes of antipsychotic drugs, their mode of action, and neurologic (“neuroleptic”) side effects have been discussed in Chap. 43.

In recent years a second generation of “atypical” nonphenothiazine antipsychotic agents that have complex effects on the dopamine and serotonin systems has been added to the standard do-
pamine antagonists, the phenothiazines and the butyrophenones. (They are atypical in that their extrapyramidal side effects are far less than that for the phenothiazines.) They all serve to calm the patient, blunt the emotional responses, and reduce hallucinosis and aggressive and impulsive behavior, leaving cognitive functions relatively intact. The main side effects, pertaining mostly to the phenothiazine group, are summarized in Table 58-1 and on page 1024 (see also the review by Freedman and chapter by Baldessarini). The antipsychotic action of these drugs is more impressive in the short and intermediate term than over the long run, although some data suggest that they are also of value in preventing relapses. Negative symptoms (apathy and withdrawal) respond less well than positive ones, and it is generally acknowledged that 10 to 20 percent of patients respond little or not at all to medication.

Clozapine, olanzapine, risperidone, quetiapine, and others listed in Table 58-2 are the more recently introduced atypical drugs with incompletely defined pharmacologic properties but with narrower affinities for certain receptors. In addition to their reduced motor side effects, they produce clinical improvement in about half of patients who have proved to be unresponsive to other antipsychotic medications. These drugs bind to and inhibit serotonin receptors and, to some extent, to dopamine receptors (Meltzer and Nash) but have a much lower affinity for striatal dopamine receptors, thus providing a major advantage—the absence of immediate or tardive extrapyramidal side effects. This has led most psychiatrists to use one of the newer drugs rather than the phenothiazines as a first choice. About 1 percent of patients treated with one of the most effective drugs, clozapine, develop leukopenia, which may prove fatal; there is less risk with the related agent, olanzapine, but leukopenia and agranulocytosis have been reported in rare instances with it as well. Orthostatic hypotension, tachycardia, fever, and hypersalivation may be troublesome in the first days and weeks of therapy with any agent in this class. Risperidone is a potent serotonin and dopamine receptor antagonist. Low doses reportedly attenuate the negative symptoms of schizophrenia (apathy, emotional withdrawal, lack of social interaction) and the incidence of extrapyramidal side effects is low provided that the dosage is kept below 6 mg daily. Typical dosages of these antipsychotic drugs are indicated in Table 58-2. In the higher dose ranges, parkinsonian features may nonetheless appear. Tardive dyskinesias, however, are

* All have the potential to cause tardive dyskinesias and neuroleptic malignant syndrome (see Table 58-1), but these complications are less frequent than with phenothiazines and haloperidol. Weight gain is common with this class of drugs.

infrequent. Common to all the drugs in the class is variable weight gain. With long-term treatment this may accumulate to 20 percent of the patient’s original weight. Hypercholesterolemia and diabetes then often emerge and may require additional treatment. In a few cases the newer generation antipsychotics have induced some obsessive-compulsive symptoms. Finally, it might be commented that according to Leucht and colleagues who performed a meta-analysis of extrapyramidal symptoms and various drugs, that low potency first-generation antipsychotics (excluding haloperidol) may have comparable complications to the new generation of drugs when dose-equivalent amounts are given. Not all clinicians agree with this perspective.

The optimal daily dose for treatment of an acute psychotic episode is in the range of 10 to 20 mg daily of haloperidol or the equivalent amount (400 to 800 mg) of a phenothiazine such as chlorpromazine or escalating doses of the newer agents as listed in Table 58-2. The administration of much higher doses of phenothiazines or haloperidol is popular with some psychiatrists but this practice entails serious risks and the advantages have not been demonstrated in controlled trials (see Kane and Marder). Attempts are made to individualize and eventually lower the dosage until the patient’s behavior suggests that a relapse is imminent. Long-acting piperazine phenothiazines, given subcutaneously every week or two, are used in patients who are unable to take oral medication or refuse to do so. Extrapyramidal side effects are troublesome and tardive dyskinesias may be even more problematic (page 94).

Antidepressants and lithium have also been used in those schizophrenic patients with prominent affective symptoms. Electroconvulsive therapy (ECT) is now seldom used except in patients who are catatonic or severely agitated or who have prominent affective symptoms, or, in exceptional instances, where there has been no response to medication.

To some extent, the extrapyramidal side effects of haloperidol and the phenothiazines can be prevented or at least minimized by the simultaneous parenteral administration of anticholinergic drugs—e.g., diphenhydramine (Benadryl), 25 mg tid—and the anticholinergic drugs used in the treatment of Parkinson disease—e.g., benztrapine mesylate (Cogentin), 0.5 to 1 mg bid. However, the latter drugs must be given cautiously for they may interfere with the action of the antipsychotic drugs and, if given in large doses, may themselves induce a toxic confusional state. It becomes necessary to treat the extrapyramidal side effects, it is usually possible to eliminate the anticholinergic drugs after 2 to 3 months without a return of symptoms. In chronically medicated patients, 20 to 40 percent of whom develop tardive dyskinesias, an increased dose of the antipsychotic drug may suppress the dyskinesia, but only temporarily. The most dreaded complication of pharmacotherapy is the neuroleptic malignant syndrome. The nature and management of tardive dyskinesias have been discussed on pages 94–95.

Supportive psychotherapy (repeated explanation, reassurance, encouragement) is of course necessary, as in any prolonged illness, and the family needs the same type of help. The physician should be understanding and sympathetic but also firm and professional. The general purpose of psychotherapy is to help the patient get a grasp on reality and to strengthen his self-esteem and psychologic defenses. Psychoanalytic therapy has little to offer as a primary mode of treatment.

Outcome With modern drug therapy and supportive psychiatric management, fully 60 percent of schizophrenic patients will recover sufficiently to return to their homes and become socially adjusted to a varying degree (about half of this group can engage in some occupation). About 30 percent remain helpless and severely handicapped and 10 percent remain hospitalized.

DELUSIONAL DISORDER (PARANOIA)

The term paranoid (para = beside, nous = mind) literally means a mind beside itself. It designates patients who show “fixed suspicions, persecutory delusions, dominant ideas or grandiose trends logically elaborated and with due regard for reality once the false interpretation or premise has been accepted. Further characteristics that differentiate pure paranoia from typical schizophrenia are formally correct conduct, adequate emotional reactions, and coherence of the train of thought” (Rosanoff). In other words, in pure paranoia (delusional disorder in DSM-IV), there is supposed to be no mental defect other than the delusional system—no dementia, hallucinations, or emotional disturbance. In past years, a large group of the mentally ill was classified as paranoid. But with advancing knowledge of mental illness, fewer and fewer have been left in this category.

The trouble that psychiatrists have taken to couch this definition in negatives implies that paranoia is frequently a feature of
other forms of mental illness, notably schizophrenia, manic-depressive disease, Alzheimer disease, Lewy-body disease, toxic or alcoholic psychosis, general paresis, etc. This fact about paranoia was known from the beginning, when Heinroth originally described it in 1818 and classified it as a limited disorder of the intellect. Krafft-Ebing, in his monograph on the subject, took pains to distinguish two syndromes: (1) “original paranoia,” developing about the time of puberty and attributable to heredity (surely paranoid schizophrenia by present-day criteria), and (2) acquired paranoia, developing in later life, particularly in the involutorial period (the condition under discussion). Kraepelin, in agreement with the ideas of Kahlbaum, distinguished between paranoia and dementia praecox but remarked that approximately 40 percent of patients who developed paranoia early in life went on to become schizophrenic. The others represented true paranoia or a closely related condition that he called paraphrenia, a term no longer used. In DSM-IV, this disorder is classified as “delusional (paranoid) disorder” and defined as a persistent delusion that is not part of any other mental disorder. Furthermore, the delusions are nonbizarre, i.e., they involve situations that could occur in real life, such as being followed, poisoned, infected, loved at a distance, deceived by a spouse, or having a disease.

Figures on the frequency of true paranoia are probably not reliable because they are of necessity based on hospital records. Doubtless there are many individuals with mild forms of the disorder who have never crossed the threshold of a mental hospital. They are relatively harmless and in their communities are judged to be mildly “cracked,” or monomaniacs. Males and females are about equally affected. Among psychiatric hospital patients, true isolated paranoia is rare (0.1 percent of admissions, according to Winokur).

Clinical Manifestations

It would be difficult in a neurology text to give an account of all the many ways in which patients with paranoia behave. A simple paradigm will suffice—that of a middle-aged man of uneasy, brooding, asocial, eccentric nature who gradually develops a dominating idea or belief of his own importance, of having in his possession special powers that make him the envy of others, who become bent on persecuting him. As the delusion grows, he becomes more preoccupied, less efficient, and increasingly suspicious of others, with a tendency to interpret every one of their words, gestures, or actions as having some reference to himself. Only when his behavior becomes noticeably bizarre or when he does something to annoy others does his condition come to medical attention. On examining such a person, one is impressed with his capacity for careful reasoning, even betraying good intelligence. Whatever the delusional theme—eroticomania (a delusion that another person, usually of higher status, is in love with the patient), grandiose, jealous, persecutory, or somatic, the last being the most common—the patient’s arguments are logical and buttressed cogently by evidence. The patients express their false beliefs with certainty and conviction and are totally unaccepting of all arguments that impugn their rationality. Also, the views of such patients about matters other than their delusions can be quite sensible.

As mentioned, the illness usually does not lead to hospitalization, and if admitted to hospital, the patient does not stay long. The querulous patients with paranoia are the most annoying. They usually remain in the community, flooding the mails with copies of documents accusing people falsely, incessantly writing to newspapers, and expressing their worthless opinions about anything and everything. As the years pass, the patient changes little, though a few such patients may later break down and begin to hallucinate and finally end in a deteriorated state much like that of schizophrenia. This trend supports Bleuler’s opinion that the illness is often a variant of schizophrenia.

Regarding causation, there have been several interesting but unverifiable ideas. The Freudian school attributed paranoia to repressed homosexuality and fixation at the narcissistic level. Meyer invoked a long-standing personality disorder, the paranoid constitution. He used the term to refer to persons with a lifelong tendency to hold biased views, to be overly concerned about what others think of them, and to attribute deliberate intentions to indifferent actions. This behavior seems but an exaggeration of a mild suspiciousness that is part of the personality makeup of many individuals. Manschreck presented a detailed discussion of the proposed psychologic mechanisms of paranoia.

The authors’ experience with pure paranoia in a general hospital has been rather limited. One sees deluded patients, to be sure, but usually their abnormal ideas have centered on self-persecution, health and bodily functions, infidelity of a spouse, theft of possessions, and the like. The claim that poisoning by carbon monoxide has left the person with ill-defined defects in concentration and other mental functions or the belief that there exists an unobservable parasitic skin infestation have been the most common delusions in our experience. One of our patients, functioning normally in every other way, carried the unshakable idea that people were sneaking into her house at night and when she was away and rearranging the furniture. Also, several physicians under our care have woven extensive or more limited delusional ideas around tenuous scientific theories; these ideas have applied to personal life events as well as physical and psychologic symptoms, and in some cases have resulted in bizarre regimens of self-medication. Rarely, a patient comes to the hospital for some other medical reason and it is found that he or she has been living quietly in the community, preoccupied with a bizarre delusional system yet appearing neither depressed nor schizophrenic. Certainly one often sees delusions in depressed patients who compensate as their depression deepens.

Sharply separated from the more or less pure delusional disorders are the ones that occur as part of a confusional state or delirium. Delusions occurring in the latter setting are characteristically bizarre, changeable, poorly systematized, and, with rare exceptions, transitory; they are associated with many other aberrations of mental function. The same can be said for delusions that occur in the early stages of a dementing disease. Such events are common, of course, in elderly persons with an incipient or well-compensated dementia (“beclouded dementia,” page 363). Rarely, one of the degenerative dementing diseases of middle and late life (Alzheimer, Huntington, and especially Lewy body) presents with a delusional disorder. Otherwise healthy persons without known mental illness may experience a brief delusional episode, notably after surgical procedure or the administration of sedative drugs. In most, there are no subsequent mental problems but a proportion of these older patients will be found to later develop dementia. Certain drugs have a tendency to produce paranoia in otherwise nonpsychotic individuals; phencyclidine, amphetamine, and cocaine are the main offenders seen in patients arriving in emergency departments, and anticholinergic drugs are often responsible in hospitalized patients. These “organic delusions” have been discussed by Cummings.
Management

The methods and objectives of psychotherapy for paranoia are discussed fully by Manschreck. We have no way of deciding whether psychotherapy has influenced this state. In a general hospital, where most of our paranoid patients have been depressed or manic, we have several times been gratified by the effects of antidepressant or antipsychotic medication. In the treatment of patients with pathologic jealousy, Mooney has found phenothiazine drugs to be useful.

From what has been said, the clinical analysis of patients with delusions requires a careful study of mood and intelligence to rule out manic-depressive psychosis and dementia. If either of these two states exists, the treatment proceeds along the lines discussed in Chaps. 57 and 21. A matter of practical importance is for the physician to evaluate carefully the nature of the delusional ideas and try to judge whether the patient is homicidal or suicidal. Occasionally, physicians and others have been killed or maimed by patients with paranoia who thought they were being mistreated.

**PUERPERAL (POSTPARTUM) PSYCHOSES**

Parturition, associated as it is with many biologic disturbances such as the effects of pain, drugs, eclampsia, hemorrhage, infection, and an abrupt hormonal adjustment, is frequently associated with a disturbance of mood. Obstetricians have repeatedly observed that the woman may feel extraordinarily well immediately postpartum, only to lapse in the following days into a weepy, depressed state in which she may be distressed by lack of feeling for her newborn infant. Usually this lasts for only a few days (“postpartum blues”), being quelled by the return home, responsibility for the infant, nursing, etc. In some patients the depressive symptoms persist for months (see later).

The period after childbirth is also one in which there is a strong disposition to psychosis. Opinion varies as to whether there is a special puerperal psychosis. Most psychiatrists believe that the psychotic break that may occur at this time is either a confusional-delirious state or a schizophreniform or depressive psychosis, and that these illnesses do not differ from those occurring at other times in life. As mentioned in the previous chapter, some authors have questioned the existence of a special depressive illness that is linked to the postpartum period, an opinion that is not supported by our clinical experience (see Brockington).

Additionally, there occurs a postpartum psychosis that cannot be categorized in this way. Usually it has its onset between 48 and 72 h after a delivery that may have been complicated by excessive bleeding or infection. The patient alternates between periods of noisy hyperactivity and of mutism and inactivity. She is disoriented and incapable of thinking clearly. The baby is sometimes rejected as not belonging to her (instances of infanticide are not unknown). Although the illness has some features of delirium, it may merge with a schizophrenic or depressive type of psychosis that persists for months. Boyd found in a series of such cases that about 40 percent were predominantly affective, 20 percent schizophrenic, and the remainder self-limited confusional psychoses of the type previously described.

In some patients, a typical depressive illness has followed each of several pregnancies, disabling the patient for weeks to months at a time. Some women with manic-depressive disease have had their early depressive attacks only after delivery. Also, as consultants to hospitals for women and babies, we had observed a number of patients with an acute postpartum schizophrenic episode. These patients were without family history or prepsychotic schizoid personality and seemed to have a better prognosis than one usually expects in schizophrenia. These are only impressions, however. The treatment of such patients follows the methods described in Chap. 57 and below.

In the diagnosis of postpartum psychosis, one must also keep in mind the possibility of eclampsia, the consequences of pituitary infarction, cerebral vein thrombosis or transitory stroke of arterial type, ergot-induced psychosis, and hypotensive-hypoxic cerebral injury.

**THE ENDOCRINE PSYCHOSES**

One of the most provocative observations in contemporary psychiatry is that apparently healthy individuals may become psychotic when they develop hypothyroidism or Cushing syndrome (or less often, adrenal insufficiency), or when they receive therapeutic doses of corticosteroids. If these conditions were no more than examples of drug-induced psychosis, they would be interesting enough. The fact is, however, that they differ considerably from the usual toxic deliria or confusional states. The syndrome, somewhat reminiscent of puerperal psychosis and some cases of “combat fatigue” seen in wartime, comprises features that are suggestive of manic-depressive psychosis or schizophrenia on the one hand and of confusional psychosis on the other. These endocrine psychoses have far-reaching medical significance, for they provide artificial models of psychoses created by the manipulation of metabolic and by exogenous factors. It is appropriate that they are in the last chapter in a book about neurology, for they provide a remarkable neurologic perspective on mental disorders.

**Corticosteroid and Adrenocorticotropic Hormone Psychosis**

First described in arthritic patients being treated with cortisone, these syndromes are now occurring far less frequently than when corticosteroids were introduced into medical practice. The psychosis usually develops over a period of a few days after the patient has received the hormone for a week or more. The features are extremely variable. Depression and insomnia are the most frequent early symptoms, but some patients become elated, agitated, excited, and talkative, as though under pressure to speak, while others are mute; or the prevailing emotional response may be one of anxiety and panic. Thinking may be slightly illogical, tangential, or incoherent. Hallucinations and sensory misinterpretations may appear. However, clouding of the sensorium and disorientation, the hallmarks of deliria and the confusional psychoses, have not been prominent. Nevertheless, the state of awareness is not altogether normal, and at times the patient is frankly bewildered. In the motor sphere there may be incessant activity or immobility, restlessness, and even negativism verging on catatonia. If administration of the hormone is discontinued as soon as symptoms appear, the psychosis subsides gradually over several days to weeks, with complete recovery.

In patients with Cushing disease, mental changes are frequent. There is in some patients a combination of affective disorder and impairment of cognitive function, usually apparent during mental status testing. Among athletes taking anabolic steroids, some develop affective and psychotic symptoms—reduced sleep, irritability, paranoid delusions, auditory hallucinations, and euphoria or depression. Mental changes in Addison disease are frequent but varied. Irritability, confusion, disorientation, and convulsions, with
or without symptoms of hypoglycemia, are the main features. The mechanisms are not well understood.

The mechanism of acute steroid psychosis is obscure. From the few available studies it has been learned that the occurrence of the psychosis is not related to the premorbid personality. Although the dosage of ACTH (corticotropin) or corticosteroid has usually been high, there has been no definite correlation between the dosage and the occurrence, severity, and duration of the psychosis. Nor does the mental disturbance appear to be related to the rapidity and intensity of the therapeutic response to ACTH and cortisone. In a study of patients with systemic lupus erythematosus by Chau and Chi, 5 percent of patients became psychotic with steroid treatment and for an obscure reason, only hypoalbuminemia was found on a statistical analysis to be an associated factor. A history of anxiety or of a family history of psychiatric disease had only a marginal predictive value steroid-induced psychosis. The notion that dexamethasone is less frequently associated with psychosis than other corticosteroids is unproven. Lithium is often effective that dexamethasone is less frequently associated with psychosis than other corticosteroids is unproven. Lithium is often effective in controlling the symptoms, allowing continuation of the corticosteroid therapy. The dose is the same as for manic states (see Falk et al).

**Thyroid Psychosis** A great deal has been said about the pervasive effects of abnormal thyroid function on all organs, including the neuromuscular apparatus and central nervous system. These effects are discussed in Chap. 40, under acquired metabolic diseases of the nervous system.

The hyperthyroid patient often shows minor changes in emotions and mentation. Restlessness, irritability, apprehension, emotional lability, and at times even agitation and a generalized chorea may occur. Either of two trends may be observed in the relatively rare thyrotoxic patient who develops a psychosis. There may be a manic state, with its characteristic increase in psychomotor activity, overtalkativeness, and flight of ideas, or there may be depression, with its somber mood, weeping, and anxiety. Visual and auditory hallucinations may be present in both groups. The clinical picture is seldom clear. Usually there is something more than simple mania or agitated depression, i.e., some clouding of the sensorium with perplexity and confusion, suggestive of delirium. The condition is said to be related to the premorbid personality, some personality types being more vulnerable, but this point is disputed; it is not directly related to the severity of the thyrotoxicosis. Careful studies of cerebral blood flow and metabolism during and after the psychosis have not been done. Treatment of the hyperthyroidism does not result in prompt arrest of the psychic disorder; recovery usually takes place over a period of months. One must distinguish this illness from other types of recurrent psychosis that happen to be coincidental with or precipitated by hyperthyroidism.

With myxedema there is a characteristic slowness and thickness of speech, drowsiness, hypothermia, mental dullness, listlessness and apathy, irritability, and sometimes suspiciousness. The patient may sleep most of the time, having to be awakened for meals. A disturbance of memory and the lack of genuine symptoms of depression, such as feelings of hopelessness and loss of self-esteem, help to distinguish the mental disorder of myxedema from that of a depressive illness. Nevertheless, unless one thinks of myxedema in cases of psychomotor retardation, the diagnosis will be missed. Reduced cerebral blood flow and metabolism have been found in myxedema; with specific therapy, these functions are restored to normal within 2 to 3 weeks.

An entirely different type of mental disturbance, characterized by intermittent delirium and stupor, associated with myoclonus and probably autoimmune in nature, may occur in patients with Hashimoto thyroiditis (page 978). The diagnosis is confirmed by the finding of certain specific circulating antibodies.

Encephalitis (continued)
limbic, 653
paraneoplastic, 585
meningitis versus, 636
postinfectious, viral encephalitis differentiated from, 636–644
Rasmussen, 653
viral. See Viral encephalitis von Economo, 653
sleep disturbance due to, 340
Encephalitis lethargica, 340, 653
Encephalomyelitis
See
Encephalopathy
disseminated, multiple sclerosis versus, 786
following rabies vaccine, 792
hemorrhagic, acute necrotizing, 792–793, 793f
myalgic, 436
paraneoplastic, 583r, 585f, 585–586
postinfectious, postvaccinal, 790–792, 791f, 791–792
Encephaloceles, 859f, 859–861
Encephalomyelitis
disseminated, multiple sclerosis versus, 786
following rabies vaccine, 792
hemorrhagic, acute necrotizing, 792–793, 793f
myalgic, 436
paraneoplastic, 583r, 585f, 585–586
postinfectious, postvaccinal, 790–792, 791f, 791–792
Encephalopathy
dialysis, 971
hepatic (portal-systemic), 967–969
hypertensive, 728–730, 729f
seen seizures due to, 290
hypoglycemic, 965–966
in meningitis, bacterial, 595
metabolic, seizures due to, 290
myoclonic, of infants (infantile opsoconus-myconus syndrome), 827–828
neonatal, hypoxic-ischemic damage and, 875–876
with nicotinic acid deficiency, 991
pancreatic, 980
punch-drunk, 763–764, 906
with sepsis and burns, 971
septic, 363
spongiform, transmissible, 653–656.
See also Creutzfeldt-Jakob disease (CJD); other specific diseases
thyroid, 978–980
uremic, 969–971
Endarterectomy. See Carotid endarterectomy
Endemic typhus, 623
Endocarditis
bacterial
septic embolism resulting from acute, 703
subacute, 608
nonbacterial, thrombotic (marantic)
cerebral embolism and, 735
embolic infarction due to, 701
Endocrine diseases. See also specific disorders
fatigue associated with, 435
myopathy, 1097, 1235–1238
psychoses, 1330–1331
Endolymph, 247f

Explosive personality, 1302r
External speech, 413
Exteroceptors, 129
Extracranial arteries, dilatation of, 325
headache due to, 146
Extradural hemorrhage, 727
Extrapyramidal disorders
acquired metabolic diseases presenting as, 975–976
congenital, 877–879
dysarthria, 427
following head injury, 763
with hereditary metabolic disease, 830–834
progressive, acquired metabolic diseases presenting as, 975–976
Extrapyramidal motor system, 55
Extrapyramidal neurologic side effects, 1024–1025, 1328
Extremity pain, 188–190
Eye movements, 222–241
in comatose patient, 313–314
incoordination of, 77
nuclear and infranuclear disorders of, 228–241
anatomy and, 228f, 228–229, 229f, 230r
cranial nerve lesions and, 230–234, 231r, 232f
of eyelids and blinking, 239–241
mixed gaze and oculomotor paralysis, 236–237
nystagmus, 237–239
painful ophthalmoplegia, 234r, 234–236, 235r
strabismus, 229–230
supranuclear control of, 222–228
anatomy and physiology of, 222–223
of horizontal gaze, 223–224
paralysis of conjugate gaze and, 226–228
testing of conjugate gaze and, 225–226, 226r
of vertical gaze, 224–225, 225f
vestibulocerebellar influences on, 225
Eyelid disorders, 239–241
Eyestrain headache, 145
F
F wave, 1100
Fabry disease, 737, 839, 1154r, 1159
polyneuropathy and, 1159
stroke associated with, 839
in children, 709
Facet joints, 168
Facet syndrome, back pain with, 180
Facial hemiatrophy, 1183–1184
Facial myokymia, hemifacial, 1184
Facial nerve, 1180–1185
anatomy of, 1180–1181, 1182f
hypsersensitivity of, 1184–1185
injury of, with head injury, 749
Facial-oral apraxia, 49
Facial pain
of dental origin, 165
of sinus origin, 165
with stroke, 738
of uncertain origin, 165
Facial palsy, 1181–1183
Bell’s, 240, 1181–1182
bilateral, 1183, 1195
congenital, 880
in HIV/AIDS, 656
supranuclear forms of, 1183
Facioscapulohumeral muscular dystrophy, 1217–1218, 1218r
Fahr syndrome, hypoparathyroidism and, 834–835, 835f
Failed back syndrome, 183
Faintness, 322. See also Syncope after head injury, delayed, 754

Fajersztajn sign, 176
Falls, in elderly people, 521
Famicloclor, for herpes zoster infections, 643
Familial amyloid polyneuropathy, 1153r
Familial myoclonus, 87
Familial paroxysmal choreoathetosis, 68
Familial spastic paraplegia, 1084
Familial tremor, 81–82, 82f
pathophysiology of, 85
treatment of, 82–83
Farber disease, 806r
in infants, 806r, 810
Fasciculation(s), 39, 1199
benign, persistent, 1277–1278
in peripheral nerve disease, 1116
Fasciculation potentials, in electromyography, 1103f,
1103–1104
Fascittis, 1241r
cosinophilic, 1210
Fast channel syndrome, 1260r, 1262
Fastigial nucleus, 73
Fat deposition, spinal, in Cushing disease, 1083
Fat embolism, 756
Fetal familial insomnia, 340–341
Fatigue, 433–437
clinical significance of, 433–434
differential diagnosis of, 436–437
effects on normal people, 433
with medical disease, 434–436
in multiple sclerosis, 780
as psychiatric symptom, 434
Fatty acid metabolism
biochemistry of, 1234
disordered, clinical features of, 1234
Fazio-Londe disease, 945r, 947
Fear, 449–450
Febrile seizures, 280, 288
Felbamate, for seizures, 295
Fenestration, in head injury, 717
Fenwal, for pain, 124r
Ferguson-Critchley syndrome, 949
Ferric chloride test, for metabolic defects, 801r
Festinating gait, 102r, 104
Fetal alcohol syndrome (FAS), 1012–1013
Fetal development, neural, 496–497
Fetal period, 493–495, 494f–496f
Fetus, viral infections of, 648
Fibrillation, 39
Fibrillation potentials, in electromyography, 1103, 1103f
Fibrocartilaginous embolism, 1072
Fibromyospiasia, retrolental, 857
Fibromyospiasia ossificans progressiva, 1283
Fibromuscular dysplasia, occlusive cerebrovascular disease due to, 704–705
Fibromyalgia, 190, 436, 1281–1282
Fibrodysplasia ossificans progressiva,
Fibrodysplasia, retrolental, 857
Fibrocartilaginous embolism, 1072
Fibrillation potentials, in electromyography, 1350

INDEX

Fludrocortisone acetate (Florinef)
Flucytosine, for cryptococcosis, 622
Fluconazole, for cryptococcosis, 622
Floppy infant, 879
Flexion injuries, spinal, 1050
Flexibilitas cerea, 306, 359
Flechig’s myelinogenic cycle, 496
Flaccidity, 41
FKRP muscular dystrophy, 1224–1225, 1225f
Folate deficiency, 997
Fluid-attenuated inversion recovery (FLAIR) imaging, 19, 20f–22f
Flumazenil, for benzodiazepine overdose, 1023
for hepatic encephalopathy, 968
5-Fluorouracil intoxication, 1041
Fluphenazine, for postherpetic neuralgia, 450
Fluphenazine, for postherpetic neuralgia, 163
Flurazepam (Dalmane), for insomnia, 340
Flutter dysmetria, ocular, 239
Focal dermal hydropisia, 858
Focal motor seizures, 275–276
Foix-Jefferson syndrome, 580f
Folatae deficiency, 997
in subacute combined degeneration, 995
Folic acid, inherited neurologic diseases responsive to, 1000f
Folie à deux, 1322
Following movements, 222–223
Foot drop, 1197
Footballer’s migraine, 150
Foramen magnum tumors, 582, 582f, 1082
Forced laughing/crying, 445f, 445–446, 450
Forearm ischemic exercise test, 1233
Foreign accent syndrome, 423
Fortification spectra, 150
Fosphenytoin (Cerebyx), for seizures, 292r, 297r
Foster Kennedy syndrome, 198, 213
Foster Kennedy syndrome, 198, 213
14-3-3 protein, 655
Fovea, 205, 206f

compression, spinal, 174 vertebral, 174
Fragile-X syndrome, 515, 864, 887–888
Friedreich ataxia, 78r, 931–934
Froehlich syndrome, 486
Froin syndrome, 14, 1080
Frontal lobes
abscesses of, 608
anatomy and physiology of, 390–391, 392f
gait and, 102r, 106
horizontal gaze palsy and, 226
lesions of, clinical effects of, 391–395
Frontonasal dysplasia, 856
Frontotemporal dementia, 372, 907–908
Fucosidosis, 806
Functional diagnosis, 3
Functional magnetic resonance imaging (fMRI), 21
Fungal infections, 620–622
of muscle, 1203
myotic aneurysms and, 727
myelitis secondary to, 1059, 1061–1062
Furosemide to lower intracranial pressure, 766 for pseudotumor cerebri, 540
G
GABA receptors, 281, 285, 286f
Gabapentin (Neurontin)
for essential tremor, 82–83
for pain, 124r, 125
for palatal tremor, 86
for seizures, 292r, 295
Gadolinium, in magnetic resonance imaging, 19
Gait
abnormal, 101–108
of aged, 102r, 106–107, 107f
“apractic,” 105, 106
cerebellar, 102r, 102–103
choreoathetotic, 104–105
in dementia, 107
drunken (reeling), 103
dystonic, 102r, 104–105
examination of patient with, 101–102, 102r
festinating and parkinsonian, 102r, 104
frontal lobe disorder, 102r, 106
hysterical, 107–108
of mentally retarded, 107
in normal-pressure hydrocephalus, 102r, 105–106
plegic (spastic), 102r, 104
rehabilitation for, 108
of sensory ataxia, 103
steppage (equine), 102r, 103–104
topping, 102r, 105
waddling (gluteal, Trendelenburg), 102r, 105
age-related changes in, 521
disorders of, in cerebellar disorders, 77
hysterical, 1298–1299
normal, 100–101, 101f
in normal-pressure hydrocephalus, 535
steppage, foot drop with, 1197
testing of, 7–8
Gait cycle, 100–101, 101f
Galactocerebrosidase deficiency, in infants, 806r, 809
Galactosemia, in neonates, 802
β-Galactosidase deficiency, infantile, 806r, 808–809
Galvanic skin-resistance test, 461
Galvanic skin-resistance test, 461
Gamma neurons, 40
Gamma knife radiation, for trigeminal neuralgia, 163
Gamma loop, 40f
Gamma neurons, 40
Gangliocytomas, 570
Gangliotubrolomas, 570

Graphophasia, 94, 931
Graves ophthalmopathy, 1235–1236
Growth abnormalities, 487
Growth hormone (GH), deficiency of, 487
Growth hormone-releasing hormone (GHRH), 481
deficiency of, 487
Guamanian Parkinson-dementia-ALS complex, 914
Guarfacine, for Tourette syndrome, 96
Guanidine hydrochloride for botulism, 1031
for Lambert-Eaton myasthenic syndrome, 1261
Guillain-Alajouanine-Garcin syndrome, 581r
Guillain-Barré syndrome (GBS), 1114, 1117, 1121–1127
acute axonal form of, 1122–1123
back pain in, 179
differential diagnosis of, 1125
historical background of, 1121
incidence of, 1121
laboratory findings in, 1123
pathogenesis and etiology of, 1124f,
1124–1125
pathologic findings in, 1123–1124
prognosis of, 1127
symptomatology of, 1122, 1122r
treatment of, 1125–1127
vertical gaze palsy in, 227
Gunn jaw-winking phenomenon, 240
Gunn pupillary sign, 242, 1184
Gustatory aura, 200
Gustatory hallucinations, 201, 277
Gustatory sense, 199–201
 gyrate and physiology of, 199–200
disturbances of, 200–201, 398
loss of, with head injury, 748
Gynecologic disorders, back pain with, 182
Gyral malformations, 855
H
H reflex, 1100
Habit spasms in akathisia, 97
in Tourette syndrome, 95–97
Hallerweder-Spatz disease, 427,
832–833, 833f
differential diagnosis of, 833–834
Hallpike maneuver, 262f
Hallucinations alcohol withdrawal and, 1008
auditory, 277
alcohol withdrawal and, 1008
pontine, 252, 398
with temporal lobe lesions, 398
emotional disturbances with, 444–445
gustatory, 201, 277
olfactory, 199, 277
in schizophrenia, 1319
visual, 405–406
Hallucinogens, 1028–1030
Haloperidol (Haldol), 1025
movement disorders due to, 64
for palatal tremor, 86
Hand, alien, 49
Haltia-Santavuori disease, 806
Hand injury, 747–768
Hashimoto encephalopathy, 978
HARP syndrome, 827
Hartnup disease, 818
Hashimoto encephalopathy, 978
Head injury, 747–768
anosmia following, 198
basal skull fractures and cranial nerve injuries, 748–749, 749f
blunt (closed), 747
brain swelling and, in children, 761
carotid-cavernous fistula, 749
cerebral concussion, 750–751
cerebral contusion and, 760
cerebrospinal fluid rhinorrhea and, 749–750, 750f
EEG in, 28, 29
epidural hemorrhage in, 757–758, 758f
intracerebral hemorrhage and, 760–761
mechanisms of, 747–752, 748f
pathologic changes associated with, 751–752, 752f, 753f
patient approach for, 753–757, 754r, 755r
for concussion followed by lucid interval and serious cerebral damage, 757
for patients who are conscious or rapidly regaining consciousness, 753–754, 756
for patients who have been comatose from the time of injury, 756–757
penetrating, 761–762
prognosis of, 768
seizures due to, 291
sequelae of, 762–765
shaken baby syndrome and, 761
sleep disturbance with, 341
subdural hematoma in, 758f–760f, 758–760
subdural hygroma in, 760
treatment of, 765–768
for patients with only transient unconsciousness, 765
for patients with severe head injury, 765–768
vertigo and, 265
Headache, 144–161
biologic events related to, 145
with brain abscesses, 608
with brain tumors, 149r, 158–159, 553
with carotid thrombosis or embolism, 669
in cerebrovascular disease, 738–739
with cervical spine disorders, 161
cluster (histamine headache; migrainous neuralgia), 148r,
155–157, 158, 162r, 339

- cavernous malformations and, 726, 726f
- dural arteriovenous fistulas and, 725f, 725–726
- primary (hypertensive), 711f, 711–716
- clinical picture in, 712–714
- laboratory findings in, 714–715
- pathogenesis of, 712
- treatment of, 715–716
- subarachnoid. See Subarachnoid hemorrhage

Intracranial hypertension. See also Intracranial pressure (ICP), elevated; Pseudotumor cerebri
- benign (idiopathic), headache with, 159
- idiopathic, 538–539

Intracranial hypotension, 541–543

Intracranial mass lesions, headache due to
- 145–147

Intracranial pressure (ICP), 530–533
- clinical signs of, in comatose patients, 315
- elevated, 531–532
  - with brain tumors, 566–571
  - causes of, 532
- management of, 766–767
- monitoring of, 532–533
- obstructive hydrocephalus and, 533–535
- treatment of, 551, 695–696
  - venous obstruction causing, 538
  - low, 541–543
  - raised, with papilledema, 211–213, 212f

Intramedullary syringomyelia syndrome, 1082

Intramuscular injections, myopathy due to, 1241r

Intraneural scarring, following nerve injury, 189

Intraocular pressure, 204–205
- raised, with papilledema, 211–213, low, 541–543

Ischemia
- brain. See Brain ischemia
- limb, critical, peripheral neuropathy due to, 1139–1140

Ischemic-hypoxic (ischemic-anoxic) encephalopathy, 959–963, 962f

Ischemic infarction, pathophysiology of, 664–667

Ischemic necrosis, of pituitary, 577

Isocortex, 386

Isomethapenete (Midrin), for migraine prophylaxis, 155

Isoniazid (INH)
- peripheral neuropathy due to, 1133
- pyridoxine deficiency due to, 996
- for tremor, 790
- for tuberculous meningitis, 612

Isopropyl alcohol ingestion, 1007

K

INDEX

Polyneuropathy (continued)
of predominantly sensory type, 1156–1157
lepromatous, 1150
motor function impairment in, 1113
nutritional, 988–990
paraneoplastic, 1131–1132
porphyric, 1129
recurrent or relapsing, problems in
diagnosis of, 1163
sensorimotor, chronic, 1120r–1121r
sensory. See Sensory polyneuropathy
with spastic paraplegia, 1157
toxic, acute, 1129–1130
uremic, 1128, 1149–1150

Polyphasic potentials, in
electromyography, 1102

Polyradiculitis, in HIV/AIDS, 656
Polyradiculoneuropathy, demyelinating,
chronic inflammatory, 1147–1149
Polyradiculopathy, 139, 1116
with or without meningeal infiltration, 1143
Pompe disease, 1230–1232,
1231r–1232r
Pontine auditory hallucinations, 252, 398
Pontine gaze palsies, 141
Pontine hemorrhage, 714
Pontocerebellar hypoplasia, 879
Pontocerebellum, 71
Porencephaly, 852
Poromania, 278
Porphyria, 1154r
Porphyric polyneuropathy, 1129
Portal-systemic encephalopathy, 976–969
Positional vertigo, benign, 261–263,
262f, 264f
Positron emission tomography (PET), of
brain and spine, 23
Postanoxic myoclonus, 89, 963
Postcentral gyrus, 399
Postconcussion syndrome, 764, 765
Posterior column(s), 131–133
Posterior column syndrome, 140f, 141
Posterior commissure, 224–225
Posterior leukoencephalopathy, 1040
Posterior lobe, of cerebellum, 71
Posterior longitudinal ligament,
ossification of, 1077
Posthemiplegic attheros, 65
Postherpetic neuralgia, 162r, 163,
643–644
Posthypoxic syndromes, 962
Postinfarction epilepsy, 738
Postoperative confusion, 363–364,
710–711
Postoperative psychosis, 1330
Postprandial hypotension, syncope and,
326
Posttraumatic epilepsy, 762
Posttraumatic headache, 158
Posttraumatic stress disorder (PTSD),
438, 439
Postural back pain, 182
Postural fixation, disorders of, 63
Postural hypotension. See Orthostatic
hypotension
Postural orthostatic tachycardia syndrome
(POTS), 327, 463
Postural tremor. See Tremor(s), postural
(action)
Posture(s)
for blood pressure and, 459, 460r
in comatose patients, 314–315
degenerative diseases characterized by
abnormalities, 915–931
Postviral fatigue syndrome, 435–436
Potassium, muscle and, 1096
Potassium channel diseases, 286
Potassium channel diseases, 286,
1266r, 1273
Pott disease, 1230–1232
Power spectral analysis, 459
Power spectral analysis, 459
for Trichinosis, 626, 1202
for sarcoidosis, 614
for tardive dyskinesia, 614
for tardive dyskinesia, 614
for multiple sclerosis, 787
